Dr William T. Greene suggested that the neuromuscular mechanism in the clinic is not so simple as in the physiology laboratory and that secondary responses often overshadow or complicate primary reactions, particularly when the central nervous system is involved. Dr Aub asked how often plumbism with poor re-creation of phosphocreatine may cause neuromuscular dysfunction. Dr Rosenbluth replied that this probably is not rare.

JEWISH MEMORIAL HOSPITAL

A regular meeting was held at the Jewish Memorial Hospital on February 27, with Dr Samuel A. Levine discussing 'Common Errors in the Diagnosis of Cardiac Conditions'. It was pointed out that heart disease is one condition in which the diagnosis is almost all important, for the treatment is usually easy or at least easy to determine. Furthermore, the treatment of heart disease is generally good, especially in large medical centers, but this is not so of diagnosis. An important and common error is the diagnosing of heart disease when none is actually present, for the patient may thus be condemned to a life of inactivity and the use of powerful drugs. To make a positive diagnosis of organic heart disease, which is not necessarily the same as heart failure, one should rely on the three cardinal signs: a diastolic murmur, cardiac enlargement and gallop rhythm. A diastolic murmur invariably means heart disease until proved otherwise, but the observer must be able to distinguish what is diastolic. Although enlargement usually indicates organic heart disease, it may occasionally be reversible and reparable, as in beriberi. Gallop rhythm, except for the rare normal systolic type, is an indication of serious cardiac damage. Other findings are usually present in heart disease but do not necessarily incriminate the organ, whereas a significant number of cardiac patients do not have any of these findings. In angina pectoris the three cardinal signs may well be absent. Here

the symptoms are important, and an accurate history is the *sine qua non*. In the absence of characteristic history all accessory diagnostic aids may need to be employed, such as studies of the pulmonary and biliary systems. Dr. Levine emphasized that apical pain is usually not coronary in origin.

If heart failure is present, the kind and amount of heart disease is not important when the treatment is the same. But one should keep looking for those rare conditions that can be cured and in which the treatment differs from the usual regimen of digitalis and diuretics. The classic examples of this are the masked thyrocardiacs for the proper diagnosis can rehabilitate a patient who might otherwise be considered hopeless. Although such people may on the surface appear perfectly normal, certain important clues indicate the true etiologic factor underlying the cardiac condition. The skin may be moist, pigmented and hyperemic; the heartbeat may be hyperactive, snappy and agile, compared to the thrusting impulse of other cardiac enlargement; there may be signs of thyrotoxicosis, such as weight loss with a good appetite, an elevated metabolic rate and a diminished cholesterol level. Dr. Levine warned that heart failure alone may give an elevated metabolic rate. An increase in the velocity of blood flow as measured by the circulation time clinches the diagnosis in the presence of congestive failure, which in all other conditions decreases the rate.

One of the most important factors in establishing a proper basis for cardiac therapy is the intelligent interpretation of signs and symptoms. Heart failure rather than heart disease should be treated, for organic disease is usually present about five times as long as failure, and early therapy is of no avail. One of the important manifestations of the failing heart is dyspnea. Here one must distinguish the shortness of breath due to obesity, bronchitis, anemia, asthenia and neurotic overventilation. Cardiac treatment does not help these conditions, and in any case should be omitted if there is not symptomatic relief. An obese person may later develop heart disease with dyspnea, but this does not indicate that previous dyspnea was cardiac in origin. Important aids in this differential diagnosis are the vital capacity and the circulation time. Dyspnea with a normal vital capacity is not heart disease. The circulation time is increased in cardiac conditions over those of pulmonary origin. Naturally, roentgenograms are of inestimable value.

A second sign of failure is rales, which should be moist and basal in comparison with the rhonchi and crepitant rales of pulmonary disease. Anterior and expiratory rales usually indicate respiratory disease. Pulmonary carcinoma may cause both dyspnea and rales, and although the proper diagnosis may not always be made, one can reassure one's consultant that the condition is not cardiac.

Edema, a third sign of failure, may be caused by increased pelvic pressure with varicose veins, nephritis and low total-protein values. The last condition may confuse the issue by being the sole cause of edema in a known cardiac patient. Since the blood volume is increased in all cardiac congestions, this may help in differentiating the edema of nephritis.

Finally, the enlarged liver of cardiac failure must be distinguished from carcinoma and cirrhosis, either of which may well occur in the presence of such conditions as hypertension. The elevation of venous pressure found in cardiac conditions is often a helpful differential point.

Dr. Levine cited additional helpful clues in the diagnosis of cardiac conditions. Women do not have coronary disease without hypertension except rarely later in life, but men may. Anginal pain is usually substernal but not

lengthy or usually present in recumbency, in contrast to aneurysm. Left-axis deviation is a common finding in patients over forty years of age, especially when there is a high diaphragm, and should therefore not be considered significant in itself. It was stated that the electrocardiogram may be helpful in diagnosis but should not be used for prognosis in the individual case. This is borne out by the fact that although an inverted T wave in Lead I usually indicates a bad prognosis, there may be occasional exceptions. Emphysema should always be considered, since it is a common cause of exertional dyspnea, rales and distant heart sounds. If rales are unilateral, they are usually at the right base in cardiac conditions.

Finally Dr. Levine re-emphasized the importance of searching for those reversible conditions that may be cured, for although each type may be rare, the total number of cases may be appreciable. Remedial arrhythmias alone may cause heart failure in a small group of patients. Arteriovenous aneurysms anywhere in the body may cause eventual cardiac failure by overwork even in an originally normal heart. These are often traumatic in origin, and are accompanied by a steady machinery murmur. Surgical results in such cases are usually strikingly effective. Then there is the beriberi heart, which is so effectively cured by appropriate vitamin therapy. And surgery may bring about a cure in constrictive pericarditis. The three questions that should be asked in any case, therefore, are: Is there heart disease? Is there heart failure? Is there heart failure for which specific therapy is available?

NOTICES

ANNOUNCEMENT

DR. A. W. GASSON announces the removal of his office from 937 Washington Street, Norwood, to 34 North Main Street, Mansfield.

BOSTON LYING-IN HOSPITAL

There will be a meeting of the Journal Club of the Boston Lying-in Hospital on Wednesday, May 7, at 8:15 p.m. in the lecture room of the hospital. Dr. Alan F. Guttmacher, associate professor of obstetrics, Johns Hopkins University School of Medicine, will speak on "Multiple Pregnancy: Certain historical, biological and clinical aspects."

Physicians and medical students are cordially invited to attend.

HARVARD MEDICAL ALUMNI ASSOCIATION

The annual meeting and dinner of the Harvard Medical Alumni Association will take place on Wednesday, June 4, at 7 p.m. at the Hermit Club, Cleveland, during the annual session of the American Medical Association. The speakers will be Dean C. Sidney Burwell, Dr. Frank H. Lahey, Dr. Roger I. Lee and Dr. Philip D. Wilson.

ANNUAL CONCERT OF THE BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will give its second annual concert on Sunday, May 11, at 8:15 p.m. in Jordan Hall. Alexander Thiede will conduct. Dr. Werner Mueller will appear as soloist.

Proceeds of the concert will be used for the establishment of a fund for a free bed in each of the following

hospitals: Beth Israel Hospital, Children's Hospital, Massachusetts Eye and Ear Infirmary and Boston Dispensary. Tickets at \$1.00 may be obtained by applying to Dr. Julius Loman, Pelham Hall Hotel, Brookline (BEA 2430).

NORFOLK DISTRICT MEDICAL SOCIETY

The ninety-first annual meeting of the Norfolk District Medical Society will take place on Tuesday, May 6, at the Hotel Puritan, Boston.

PROGRAM

6 p.m. Business meeting.

7 p.m. Dinner.

Colonel Charles W. Furlong, explorer, lecturer and writer, will speak.

Reservations for the dinner should be made by Saturday noon, May 3, and should be sent to Dr. Frank S. Cruickshank, secretary, 1247 Beacon Street, Brookline.

WACHUSETT MEDICAL IMPROVEMENT SOCIETY

The next meeting of the Wachusett Medical Improvement Society will be held at the Holden District Hospital on Wednesday, May 7, at 6:30 p.m.

PROGRAM

Clinicopathological conference.

A medical case. Drs. I. L. Cutler, J. J. Dumphy and A. R. Crane.

A surgical case. Drs. John Fallon and William Freeman.

NATIONAL GASTROENTEROLOGICAL ASSOCIATION

The sixth annual convention of the National Gastroenterological Association will be held at Hotel Commodore, New York City, May 13 to 16. May 15 has been designated New England Day, and many of the speakers will be from this district. Dr. Frank H. Lahey will address the meeting in the afternoon and will be the speaker at the banquet that night. Other New England speakers include Drs. Carl Bearse, Louis F. Curran, Herbert G. Dunphy, E. Stanley Emery, Jr., Charles A. Lamb, Charles W. McClure, William R. Morrison, George Papen, Richard H. Sweet, and Norman A. Welch, of Boston; Drs. Frank A. Cummings, Frederic V. Hussey and E. Ashlev Shaw, of Rhode Island, and Dr. Robert F. Scholl, of Connecticut.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, MAY 4

- MONDAY, MAY 5**
12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.
- TUESDAY, MAY 6**
*9:10 a.m. Pneumoencephalography. Dr. Kurt Goldstein. Joseph H. Pratt Diagnostic Hospital.
12:15-1:15 p.m. Clinicoradiologic conference. Peter Bent Brigham Hospital amphitheater.
- WEDNESDAY, MAY 7**
*9-10 a.m. Utericaria. Dr. E. A. Brown. Joseph H. Pratt Diagnostic Hospital.
*12 m. Clinicopathological conference. Children's Hospital.
*5:15 p.m. Multiple Pregnancy. Certain historical, biological and clinical aspects. Dr. Alan F. Guttmacher. Journal Club. Boston Lying in Hospital.

- THURSDAY, MAY 8**
*9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- FRIDAY, MAY 9**
*9-10 a.m. Marked Hyperthyroidism. Dr. Oliver Cope. Joseph H. Pratt Diagnostic Hospital.
- SATURDAY, MAY 10**
*9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- *Open to the medical profession

BOOK REVIEWS

Social and Biological Aspects of Mental Disease. By Benjamin Malzberg, Ph.D. 8°, cloth, 360 pp., with 170 tables and 19 graphs. Utica, New York: State Hospitals Press, 1940. \$2.50.

In this book the author publishes a series of papers written during the last several years. It is a very valuable contribution to the subject of psychiatry and provides a large mass of basic data for psychiatrists and students of mental disorders. Dr. Malzberg believes that the increase in patients on the books of the New York State

hospitals between 1909 and 1935 indicates an increase in mental disease in that state. The larger number of patients thus revealed might be due to an increasing length of hospital stay or to changes in parole criteria that would increase the number of patients on the books.

The chapter, "Age and Mental Disease," is very interesting and gives a number of graphs presenting the rate distribution for various psychoses. A chapter on environment brings out the fact that mental disease in patients from urban areas is very much higher than in patients from rural areas. The chapter on marital status shows that the married population had much lower rates of mental disease than any of the other groups. Foreign-born persons showed the higher admission rate for mental disease (108 per 100,000) and the native-born a lower rate (91 per 100,000). In a chapter entitled, "Race and Mental Disease," the writer shows the age ratios and psychoses in Italians, Germans, Irish, English, Scandinavians and Negroes. Studying mental disease in relation to birth order, the author found no evidence that the first-born children are at a disadvantage so far as the appearance of a mental disorder is concerned. In studying economic status, it was found that unskilled workers appear to have the highest rate for mental disease. Illiteracy was also found to be related to high admission rates.

This volume makes a valuable addition to the literature of psychiatry and will probably be used as source material for some years to come. Oddly enough, its material parallels the data for Massachusetts published the same year by Dr. Neil A. Dayton.

Psychiatric Clinics for Children, with Special Reference to State Programs. By Helen Leland Witmer, Ph.D., Smith College School for Social Work. 8°, cloth, 437 pp. New York: The Commonwealth Fund, 1940. \$2.50.

This book provides information for those interested in child-guidance clinic services. For the last nine years the National Committee for Mental Hygiene, through members of its field staff, has been conducting an evaluation of programs that offer this service throughout the country. The philosophy, the practice, the objectives and the achievements of clinical child psychiatry are studied. The results of this analysis, covering several years, are presented in this volume.

Part I describes the background of clinical child psychiatry in the United States. Part II discusses clinics financed by state governments, and evaluates typical policies. Part III suggests that the present difficulties of such clinics are traceable to lack of well-defined objectives and examines the alternative possibilities. The book ends with a list of basic requirements that, the author believes, must be met if a program of clinical psychiatry is to be successful.

The author is evidently thoroughly convinced of the superiority of the classic child-guidance clinic as developed in New York. The habit clinics, as developed in Massachusetts by Dr. Douglas A. Thom, and the traveling psychiatric school clinics, initiated by the late Dr. Walter E. Fernald, are discussed but briefly. The latter are described as "not wholly satisfactory." It seems that a traveling school clinic service which makes possible the examination of over 8000 children in about two hundred and seventy cities, towns and villages of Massachusetts each year should deserve serious consideration. At the end of 1940 the clinics mentioned had examined over 130,000 retarded and problem children in the public schools. The author gives as one of the reasons for the popularity of the Massachusetts school clinics that the recommendations advise the school authorities how "to get rid of the child."

Chapter 13, on psychiatric service for the feeble-minded, is particularly weak and shows a lack of understanding of the subject. The author gives the impression that he is exasperated because the condition of mental deficiency cannot be explained by the Freudian philosophy.

There is a grave question in the minds of many whether or not the heavily staffed, cumbersome and expensive child-guidance clinic is a practical solution to present needs for psychiatric services for children. With thousands of children needing assistance, the existing child-guidance clinics serve hundreds. In essence this book is a plea for the continuation of the old order.

Principles of Hematology. By Russell L. Haden, M.D. Second edition, thoroughly revised. 8°, cloth, 362 pp., with 167 illustrations, 1 colored plate and 30 tables. Philadelphia: Lea and Febiger, 1940. \$4.50.

The second edition of Haden's book has necessitated reprinting and revision within little more than a year. It is essentially a book for the general practitioner. Its chief features are its simple presentation, the large number of mechanistic diagrams of blood formation and blood destruction, and the illustrative cases. There are many excellent photomicrographs.

The text is unfortunately rather scanty, and there is frequent evidence of careless writing. In the interest of simplicity, thoroughness is frequently sacrificed, and occasionally a dogmatic attitude crops up. The volume in dex is still emphasized, although it is being more and more replaced by the corpuscular volume. There is no discussion of bone-marrow findings in various conditions, although it is certain that the intelligent practitioner would like to know about them. The anemias are discussed from illustrative cases only. The photoelectric-cell technic for the estimation of hemoglobin is not mentioned.

Despite these failings, a careful reading of the book by the practitioner should certainly advance his understanding of the field of hematology. The reviewer believes, however, that even the general practitioner should have the benefit of thoroughness in any subject he chooses to inquire into. This must be looked for in other books.

Haemorrhoids and Their Treatment: The varicose syndrome of the rectum. By Kasper Blond, M.D. Translated by E. Stanley Lee, M.S., F.R.C.S. 8°, cloth, 140 pp., with 49 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$4.50.

The author of this work has had an extensive experience with rectal and anal disease in Vienna and in clinics in other cities. His methods of treatment and his results are worthy of close study. He is an exponent of treating hemorrhoids, prolapse, fissure, pruritus and anal fistula by the injection method. The author believes all these conditions are due to one etiologic factor, — venous congestion and its complications, — an assumption that seems to be an oversimplification.

The operative treatment of anal fistula is deprecated because of the many failures; however, such poor results, in the opinion of the reviewer, are due not to the operation but to inadequate or improper postoperative care of the patient.

The methods and technics of the author are excellent, but few will agree wholly with his theories of the causation of anorectal disease.

NUMBER 19

PRECANCEROUS DERMATOSES*

OLIVER S. ORMSBY, M.D.†
CHICAGO

PRECANCEROUS dermatoses as discussed in this paper include a group of lesions that are not malignant but in or on which cancer may develop.

The most important precancerous conditions are the keratoses. This group includes senile, arsenical, tar, paraffin and roentgen-ray keratoses and leukoplakia. The precancerous dermatosis of Bowen is probably a distinct type of epithelioma, although much confusion exists as to its limitations. Erythroplasia of Queyrat is a classic precancerous disease.

Carcinoma is a prominent feature in xeroderma pigmentosum, and malignant growths frequently develop in or from pigmented moles. In sailors, farmers, mountaineers and other persons much exposed to the sun's rays and all weather conditions, a presenile dystrophy characterized by atrophy, pigmentation, telangiectasis and keratosis occurs and not infrequently terminates in multiple epithelioma. Whether or not Paget's disease is cancerous in the stage of dermatitis is still a debated question, but there is no doubt that it should be so viewed and treated. The association of kraurosis vulvae and carcinoma is well known, and malignant transformation is of great importance in this disease.

Epitheliomas develop occasionally in keratosis follicularis (Darier's disease), lupus vulgaris, lupus erythematosus, psoriasis and scleroderma, in old scars, particularly those following burns, on cutaneous horns and callosities and in wens, dermoid cysts, ulcers and fistulas.

Montgomery¹ would limit the term "precancerous dermatosis" to Bowen's precancerous dermatosis, senile keratosis, arsenical keratosis, tar and radiation keratosis, leukoplakia and the erythroplasia of Queyrat. He states that in 20 per cent

or more of these cases epitheliomas of squamous type develop.

HYPERKERATOSES

Senile Keratosis

The most significant form of keratosis terminating in cancer and the one to which the term "precancerous" is appropriate is the senile keratoma of Besnier. In a paper presented at the International Congress of 1896 in London, Dubreuilh² gave a clear description of circumscribed keratosis and adopted Besnier's title, which Eller and Ryan³ consider a misnomer — they prefer the term "senile keratosis."

These lesions are seen in people past middle life, oftener in men than in women, and occur on surfaces exposed to the sun and changing weather conditions. The common regions affected are the forehead, the temple, the upper part of the cheeks, the nose, the dorsal surfaces of the hands, the sides of the neck and the ears. The growths are occasionally seen elsewhere. They are pinhead to dime-sized, moderately elevated, sometimes slightly greasy but more frequently dry and hard, firmly adherent, yellowish-brown or black crusts; when forcibly removed, they present on the undersurface numerous horny spines, which have projected into the dilated mouths of the underlying follicles. The skin beneath is uneven, moist and red, bleeds readily and is sometimes superficially ulcerated. The lesions commonly present no inflammatory symptoms, but while they are changing into true epitheliomas some inflammatory reaction may be noted. The course is variable. The process may remain for years without change. Some growths are gradually transformed into epitheliomatous ulcers that gradually enlarge, whereas others become more elevated and wartlike and present the clinical characteristics of a papillomatous epithelioma.

These lesions are often found in association with other changes characteristic of the senile skin, such as atrophy, hyperpigmentations and unusual

*Presented at the New England Postgraduate Assembly, Cambridge, Massachusetts, November 14, 1940.

†Clinical professor and chairman, Department of Dermatology, Rush Medical College, University of Chicago; dermatologist, Presbyterian Hospital.

dryness, with or without scaling and with more or less persistent seborrheic patches.

The histopathology of senile keratosis was studied early by Hartzell⁴ and Fordyce⁵ and later re-studied, together with verruca senilis (verruca seborrheica), by Freudenthal,⁶ Eller and Ryan,³ Hookey⁷ and Montgomery and Dörffel.⁸ This condition presents a marked hyperkeratosis, which consists of closely packed horny lamellae, and an irregular acanthosis, the basal layer being poorly defined and its cells containing a variable amount of pigment. There are a variable number of mitoses in the epidermal cells, and dyskeratotic phenomena are seen. In the upper cutis there occurs an inflammatory reaction of varying degree of intensity, indicated by vascular dilatation, and a cellular infiltration consisting chiefly of lymphocytes, together with a few plasma and connective-tissue cells. Some basophilic degeneration of the cutis also occurs.

The senile flat wart, verruca seborrheica, often closely resembles the senile keratoma. The lesions of verruca seborrheica occur usually at or past middle life and are found chiefly on the back, over the shoulders, on the chest, on the abdomen at the waistline and occasionally on the face and neck. They are flat, moderately elevated, oval or round, pea to small-coin sized, gray, yellow, brown or black, and present a soft granular surface. The friable greasy crust is easily removed, revealing a red granular or slightly papillomatous base. The lesions may be accompanied by itching, which at times may be severe. Unlike the senile keratoses, they rarely undergo malignant transformation. Occasionally, the surface is smooth, when the process resembles a nonhairy pigmented mole; this type has been designated "nevoid keratosis."

In addition to the typical verruca seborrheica described above, there occurs a hyperkeratotic seborrheic keratosis in the form of scaling pigmented patches that closely resemble senile keratoses. In these the scales are waxy and the skin is thickened, sometimes slightly verrucous; their color is yellow brown to brownish black, and they are found on the face, scalp and upper portion of the trunk in elderly people. These not infrequently undergo malignant transformation.

The characteristic changes consist in hyperkeratosis, acanthosis, horny cysts and hyperpigmentation. The epithelial hyperplasia occurs in the form of a loose or solid network of epithelial cells. Islands of connective tissue are enclosed in this network, owing to the irregular acanthotic prolongation of the rete. Numerous horny cysts are present and are characteristic of the affection. Hyperpigmentation occurs, the melanin granules

being scattered throughout the epidermis as well as being present in the basal layer of epithelial cells; they are also found in the cutis. No dyskeratotic changes are found in the epithelial cells. The cutis may show a moderate inflammatory reaction.

Hookey⁷ summarizes the changes as follows: senile keratoses are characterized by hyperkeratosis and irregular acanthosis, with dyskeratotic phenomena and secondary inflammatory reaction; seborrheic keratoses are distinguished by hyperkeratosis and irregular acanthosis with the formation of an epithelial network, absence of dyskeratosis, a mild inflammatory reaction and, usually, increased pigmentation. The chief points of distinction clinically between the two conditions are their location and appearance. Senile keratoses occur mainly on the forehead, the upper portions of the sides of the face, the ears, the sides of the neck and the dorsums of the hands. The lesions are hard, firmly adherent crusts, with horny spines on the undersurface, which fit into the open mouths of follicles beneath. The surface beneath the crust is moist and red, bleeds easily and is sometimes superficially ulcerated. The seborrheic keratoses are found on the trunk, front and back, the abdomen and, less often, the face and neck. These lesions are soft and granular and easily removed, revealing a soft granular or slightly papillomatous base. The senile keratoses often undergo malignant transformation and are therefore precancerous, whereas the seborrheic keratoses rarely undergo this change and are not considered precancerous.

The lesions of keratosis senilis may be removed by softening with a keratolytic (salicylic acid) ointment for a few days, then curetting the surface and refrigerating with carbon dioxide snow, or trichloroacetic acid may be employed. Diathermy and electrocoagulation are also used. If malignant change is already present, one or the other of the last two methods or surgical excision is preferable.

As a rule, the removal of seborrheic keratoses or warts is necessary only for cosmetic purposes. When they are numerous and large and limited to the trunk, complete removal is not necessary. They may be reduced in size and made less conspicuous by the use of an ointment containing 3 per cent salicylic acid and 5 per cent sulfur. If complete removal is desired, they may be curetted and frozen with carbon dioxide snow, or trichloroacetic acid may be applied. Roentgen-ray therapy is also efficacious.

Keratoses occur quite commonly on the lips, especially the lower. They are often small or oval lesions, moderately elevated. At times they are

linear and may cover half the surface of the lip in the form of a narrow band. They usually occur in men around middle life and older, although they are not infrequently seen at an earlier age. They are persistent and often undergo malignant ulceration. They should always be viewed as having dangerous potentialities, and they should be thoroughly removed as early as possible.

LEUKOPLAKIA

Leukoplakia, as seen in the mouth, occurs as whitened areas of varying size and diverse outline. There may be one or several patches on the surface of the tongue, beneath the tongue, on the buccal mucosa, particularly behind the commissures and over the area opposite the molars, on the gums, on the lips and on the hard palate. At times the lesions occur profusely over a large portion of the buccal cavity. The patches are white or grayish white, thickened in varying degrees, often rough. Erosions occur in patches when the superficial covering is shed. At times the patch becomes verrucous, fissured and vegetating. It is not known in what proportion cancer develops. The process occurs in both syphilitic and nonsyphilitic persons. The chief lesion from which it is to be distinguished is lichen planus, in which the white areas are linear and striate on the buccal mucosa and consist of white papules on the tongue. The presence of cutaneous lesions of lichen planus is a valuable diagnostic point. Occasionally a syphilitic interstitial glossitis with atrophy is associated with leukoplakia. The use of tobacco, both by smoking and chewing, is often an etiologic factor.

In treatment, cessation of the use of local irritants is primarily indicated, the first one being tobacco. Hot and cold food, condiments and vinegar are to be avoided. Electrodesiccation, the electric cautery and radium are the most efficient methods of direct removal. In extensive quiescent cases, palliative treatment is recommended. Partial removal is likely to induce malignant change.

Kraurosis vulvae usually occurs in women of advanced age or at the menopause, or in younger women in whom the condition has been produced by surgical removal of the uterus or ovaries. It is essentially a sclerosing atrophy of the mucocutaneous structures of the vulva. In advanced cases it is characterized by the complete, or almost complete, disappearance of the labia minora, the frenulum and the clitoris, with flattening and reduction in the volume of the labia majora; rigidity of all the vulvar tissues and atresia of the vaginal orifice are also noticeable. The retracted tissues may be whitish, yellowish, reddish or bluish. A characteristic glistening or varnished appearance

may be present. The lesion is usually preceded by intense itching, which may persist, although in some late cases there is a loss of cutaneous sensibility. Taussig⁹ states that 75 per cent occur at the menopause, and that the remainder have some disturbance of ovarian function. True leukoplakia may occur as a complication; if so, cancer often follows.

This condition is to be distinguished from simple leukoplakia of this region, which is similar to that seen in the mouth, and from pruritus with lichenification (neurodermatitis), which produces a whitish thickening of the vulva. When the last condition is present, the usual picture of neurodermatitis is apt to extend over the pubes and down over the inner aspects of the thighs.

The treatment of kraurosis, with or without leukoplakia, is surgical. Taussig⁹ believes that the incidence of cancer can be reduced 50 per cent by complete vulvectomy for leukoplakic vulvitis.

Montgomery and associates¹⁰ give the following characteristic histologic features of leukoplakia: hyperkeratosis; hypertrophy of the stratum granulosum; atrophy of the rete mucosum; liquefaction necrosis of the basal-cell layer; edema and homogenization of the connective-tissue fibers; cellular infiltration, largely lymphocytic, of the mid-cutis; and subsequent atrophy of the cutis and subcutis.

PRECANCEROUS DERMATOSIS OF BOWEN

In 1912 Bowen¹¹ recorded two cases of chronic atypical epithelial proliferation with unique clinical characteristics. Since that time, numerous cases have been recorded, a number of which have differed materially from the original cases reported. As the term denotes, Bowen believed that malignant transformation was probable, and in a number of cases since recorded such transformation has occurred.

In Bowen's cases there were lesions in well-defined patches. The early lesion was a firm pale-red papule covered with a thickened horny layer or a cornified crust. Beneath the crust the surface was papillomatous. Enlargement of the papule formed lenticular or rounded nodular lesions that were discrete or grouped and confluent. The lesions at the margins of the patch had an annular or serpiginous outline. The patches increased in size by the formation of new lesions at the periphery. The clinical appearance suggested a late nodular syphiloderm.

The chief histopathologic changes occur in the epidermis. There is a marked proliferation of the rete, with distortion of its cells. There is amitotic cell division, with clumping of the nuclei, and individual cell keratinization, with the forma-

tion of giant epithelial cells. Vacuolization of the cells occurs, simulating the cell of Paget's disease. The intercellular bridges are preserved, and the basal layer is intact. In the upper corium there is a vascular dilation with a cellular infiltration consisting of lymphocytic and plasma cells.

The process is to be distinguished from extramammary Paget's disease and superficial epitheliomatosis. The localization of the lesions described by Bowen, with their papular and nodular character and serpiginous configuration, makes the clinical distinction from the superficial red scaling or crusted patches seen in Paget's disease.

In all cases, surgical renoval is recommended.

PIGMENTED MOLES

The most dangerous type of mole is flat and slaty or blue black. These moles are commonly seen near the eyes and on the feet. They sometimes undergo malignant transformation without apparent injury. As a rule, however, chronic irritation, trauma, application of caustics or incomplete surgical removal is the immediate cause of malignant change. The moles that are large, brown, flat or elevated, and hairy or free from hair are not usually a menace unless irritated. I have seen quite a large number of generalized fatal cases of malignant melanoma that have followed incomplete surgical removal or cauterization (usually with an acid) of a pigmented mole. As a rule the malignant metastatic tumors are classed as nevocarcinoma or malignant melanoma. Nomland¹² described multiple basal-cell, pigmented epitheliomas developing on basal-cell pigmented nevi.

ERYTHROPLASIA OF QUEYRAT

This is a rare lesion, originally described by Fournier and Darier¹³ as a precancerous condition. It occurs on the glans, the prepuce and the vulva, as well as on the buccal mucosa, including the tongue, cheeks and lips. The lesions are well-defined areas with brilliant-red velvety surfaces. The condition progresses slowly and indefinitely, and it is resistant to local treatment. The cause is unknown, although the process is often associated with syphilis. Conditions from which it must be distinguished are superficial epithelioma, tuberculosis and syphilis.

The characteristic histologic change consists in marked acanthosis, with some cellular infiltration in the upper cutis. Occasionally, dyskeratotic changes, such as those seen in Bowen's disease, occur. Carcinoma always follows, unless the growth is totally destroyed in its early stages.

KERATOSIS FOLLICULARIS

Keratosis follicularis (Darier's disease) is a classic keratotic disease, first described by Morrow¹⁴ and shortly thereafter independently studied by Darier,¹⁵ of France, and White,¹⁶ of America. It was early studied intensively on account of peculiar round bodies, found on microscopic examination, which were believed to be parasites (psorosperms). In his histologic examination of White's original case, Bowen¹⁷ described these bodies as epithelial cells that had undergone anomalous cornification. The disease occurs at all ages, not infrequently beginning in infancy, and is also seen in elderly people. Males are attacked more frequently than females, and heredity is a factor in its production. Trimble,¹⁸ for example, recorded 5 cases in three generations.

The disease is characterized by an eruption beginning as papules, which soon become crust covered and by coalescence produce papillomatous vegetating and tumorlike growths. The eruption is usually most extensive on the trunk, especially in the axillary and inguinal regions and around the neck. It also occurs on the head and extremities. The vegetating and papillomatous lesions are found chiefly in the axillary and genital regions and behind the ears. Seborrhic crusting occurs in the scalp. The early lesion is essentially a follicular keratosis.

The essential pathologic process is a hyperkeratosis of the follicles, which are filled with horny material. The round bodies are found between the prickle cells of the rete malpighii. The disease is uncommon, although numerous examples have been seen all over the world. Wende¹⁹ recorded the first example of malignant transformation seen in this affection.

Treatment is unsatisfactory. Amelioration of the symptoms may be effected with the use of keratolytic ointments and roentgen-ray therapy. The prognosis as to recovery from the disorder is unfavorable, but as to a serious termination it is good, aside from the possibility of malignant transformation.

PAGET'S DISEASE

This disease, as seen on the nipple, was first described by Paget²⁰ in 1874. Extramammary cases were reported many years later (Hartzell²¹).

The nipple cases usually occur on the breasts of women, although some have occurred in men. On the nipple the process is characterized by redness and scaling, which later becomes more marked; the redness deepens, and the surface becomes granulating and exudes a clear viscid secretion forming

crusts, accompanied by sensations of heat, burning and itching of varying intensity. The inflammatory area is well defined, and as time progresses the process extends deeply, forming a circumscribed infiltration of the skin that on palpation suggests a large sized coin or button in the substance of the areola and surrounding parts. The nipple becomes flattened or retracted. Sooner or later carcinomatous infiltration occurs in the substance of the breast. The course of the disease is usually slow, and no attempt at healing of the eczematous process on the nipple occurs.

Extramammary cases have been seen on the penis, scrotum, buttocks, vulva and perineum and in the axilla and numerous other situations. The clinical symptoms are those seen on the nipple. It is likely that the major portion of the lesions on the trunk are examples of superficial epitheliomatosis, which is usually of the basal-cell type.

The characteristic histologic changes consist in edema and hypertrophy of the epidermis, in which peculiar cells are found, together with an inflammatory cellular infiltration in the corium. There is marked hypertrophy of the rete with downward growth of its pegs into the corium. Peculiar double-contoured cells of large size are found in varying numbers. These cells are vacuolated, round or irregular, and often contain two or three nuclei that show varying changes in form, size and location. The Paget cells resemble the dyskeratotic cells found in Bowen's disease, but they have no intercellular bridges. They were formerly considered by Drier to be coccidia or psorosperms, but it is now known that they are cellular degenerations.

A cellular infiltration, consisting of leukocytes, small connective tissue, plasma and a few mast cells, is found in the corium, together with dilatation of the blood vessels, and in the areas of infiltration the collagen and elastin are more or less destroyed. The retraction of the nipple is due to sclerosis occurring around the mammary ducts, the latter being involved in malignant infiltration early in the process in some cases. The subsequent carcinoma may develop either from these ducts or glands beneath or from the surface epithelium.

The histology of the extramammary cases corresponds to the above in most particulars. In some cases the cellular exudate is less pronounced. The presence of the Paget cell and other characteristics identify the condition histologically. Montgomery²² believes that most of the cases reported as extramammary Paget's disease, particularly those on the scrotum, perineum and penis, were histologically frank squamous cell epitheliomas showing individual cell keratinization, whereas those on other

parts of the body histologically were basal-cell epitheliomas, the lesions of Bowen's disease or metastatic carcinomas.

Paget's disease of the breast is distinguished from eczema by its intractable character, its localization to the nipple area, its deeper infiltration—shown clinically by a feeling of hardness revealed by palpation—and, finally, its accompanying malignant growth in the substance of the breast. The reported extramammary cases on the trunk are practically indistinguishable from superficial epitheliomatosis in its crusted type.

Paget's disease of the breast requires surgical extirpation. Complete removal of the breast and accompanying lymph nodes is recommended. The extramammary type may be excised or treated with radium or roentgen rays.

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is a rare disease that begins in childhood and is characterized by hyperpigmentation, atrophic areas, telangiectases and warty and malignant growths. This disease was first described by Hebra and Kaposi²³ in 1870.

The eruption occurs largely on exposed surfaces, including the face, neck, upper chest, hands and forearms. Other areas are occasionally invaded. Sunburn has initiated the process in several cases. It is distinctly a family disease, being present in two or more members as a rule. The earliest symptom may be an erythema or dermatitis. Following this, or independent of it, frecklelike lesions develop. These become numerous, are of variable sizes and present different shades of yellow and brown. Interspersed between these lesions, variously sized whitish atrophic areas or cicatriform patches develop. Telangiectases and small angiomas are common. Flat or convex warty growths also develop, and these resemble senile keratoses. They are pea sized or larger and are scattered among the pigmented and telangiectatic lesions. At a later date malignant growths appear, and various forms occur, the chief of which is carcinoma. Ectropion is common, with its associated photophobia and lacrimation, and often causes ulceration on the face. Keratitis is common, and nodules and opacities occur in the cornea, causing obstruction of vision.

The progress of the disease is usually slow, though death from marasmus may occur within a few months. Malignant transformation usually occurs after many years and results in a fatal termination. A striking characteristic of the disease is its resemblance to the changes seen in the senile skin. Aside from the fact that it is a family affection and apparently is the result of the action

of the sun's rays on a peculiarly sensitive skin, nothing is known of its cause.

All the changes seen microscopically are closely simulated in sailors' skin and in chronic roentgen-ray dermatitis. The malignant growths oftenest seen are basal-cell epitheliomas. In addition, melanoepitheliomas, trichoepitheliomas, round-cell, spindle-cell and giant-cell sarcomas, endotheliomas, peritheliomas and angiosarcomas have been described, as well as fibromas and angiomas. A detailed histologic description of the disease and its sequelae is impossible.

Xeroderma pigmentosum presents such striking symptoms that it is readily recognized. The early date of onset and the limitation of symptoms to exposed surfaces, together with the combination of pigmented lesions, telangiectases, atrophic spots and areas, associated with the peculiar photophobia and lacrimation, are seen only in this affection.

Treatment is unsatisfactory. Life may be prolonged, however, by preventing exposure to the rays of the sun. General hygienic care is important. The malignant growths respond well to treatment with radium and roentgen rays. Surgery is often indicated.

In most cases the outlook is grave; however, with careful treatment life may be prolonged several years.

OTHER PRECANCEROUS DERMATOSES

Arsenical keratoses develop in people who have used the drug over long periods for the relief of cutaneous dermatoses, such as psoriasis and dermatitis herpetiformis. They are usually associated with pigmentation. Multiple epitheliomas not infrequently develop on these keratoses. I have observed one case in which more than a dozen epitheliomas, both superficial and deep, developed among hundreds of keratoses and hyperpigmented lesions. The malignant transformation occurred chiefly on the hands, limbs and scrotum.

Keratoses occurring in tar and paraffin workers are often associated with acneform lesions and areas of dermatitis, together with scars, the previous site of epitheliomatous ulceration that healed

spontaneously. Cancer from tar is an industrial disease that has been reported in England.

Chimney-sweep (soot) cancer, usually occurring on the scrotum, is only of historic and scientific interest here, since it has been seen chiefly in England and is reported rarely at present.

Roentgen-ray keratoses occur in chronic radio-dermatitis and, unfortunately, are seen quite often. They occur in the skin of unprotected operators most frequently, but occasionally in others. They are usually associated with areas of atrophy and telangiectasia, and not infrequently undergo malignant transformation. Electrodesiccation, electrothermy or excision is recommended for their removal.

ACUTE TYPHOIDAL CHOLECYSTITIS AND CHOLELITHIASIS OCCURRING FORTY-THREE YEARS AFTER TYPHOID FEVER*

Report of a Case

THOMAS W. BOTSFORD, MD†

BOSTON

ACUTE suppurative cholecystitis has been recognized as a complication of typhoid fever since the report of a case by Gilbert and Girode¹ in 1890. In 1898, Cushing² pointed out that *Eberthella typhosa* may be responsible for the formation of gallstones. It is also well understood that persons may harbor *E. typhosa* in their biliary or intestinal tracts for many years and thus act as carriers of typhoid fever. Nevertheless, the occurrence of acute suppurative cholecystitis due to *E. typhosa* over forty years after the original attack of typhoid fever is sufficiently unusual to merit recording, and such a case is presented.

CASE REPORT

Mrs. F. F., a 64-year-old widow, entered the Medical Service of the Peter Bent Brigham Hospital on August 1, 1940, under the care of Dr. Reginald Fitz, she complained of pain in the right upper quadrant, nausea and vomiting of 2 days' duration. In 1897, the patient had typhoid fever, and several weeks later an attack of abdominal pain was diagnosed as typhoidal cholecystitis. In 1911, she was ill for 3 weeks with abdominal pain and jaundice. In 1926 and again in 1937, she suffered attacks of pain in the right upper quadrant of the abdomen, indigestion, nausea and vomiting. Intravenous cholecystograms in 1927 showed no definite gall bladder shadow. Cholecystectomy was advised but was refused. There had been no further attacks of abdominal pain until 2 days before entry, when the patient complained of right epigastric pain and indigestion. These symptoms were at first relieved by soda, but the day before entry the pain became severe and radiated to the right shoulder. She became nauseated and vomited repeatedly. The bowels had moved twice since the onset, but their color was not noted. There had been no recent chills or jaundice. The patient had avoided fatty foods for many years, because they gave her indigestion.

Past history showed that the patient underwent subtotal thyroidectomy in 1925 for goiter with hyperthyroidism. She was in the hospital in June, 1940, because of bilateral bronchopneumonia. For 10 years she had had dyspnea on exertion.

There was no family history of typhoid fever, diabetes, tuberculosis, cancer or blood diseases.

Physical examination showed an extremely ill, markedly obese woman. The rectal temperature was 102°F, and the pulse rate was 140. The blood pressure was 145/60. There was marked spasm and tenderness over the entire right side of the abdomen, with maximum tenderness in the right upper quadrant. The tongue was covered by a heavy yellow coat. There were moist rales at both lung bases. The heart was not enlarged, and the sounds were

regular and of good quality. Rectal examination was negative. Generalized arteriosclerosis was evident.

Blood examination showed a red cell count of 4,200,000 with a hemoglobin of 85 per cent (Sahli). The white cell count was 19,500 but gradually decreased to 8500. The blood smear showed 83 per cent polymorphonuclear leukocytes, 14 per cent lymphocytes, and 3 per cent mono-

TABLE 1 Reports on Cultures

MATERIAL	DATE TAKEN	REPORT
Pus from abscess (at operation)	August 16	<i>Eberthella typhosa</i> (pure culture)
Pus from wound	August 23	<i>Staphylococcus aureus</i>
Bile from drainage tube	August 28	<i>E. typhosa</i> (pure culture)
Center of gallstone	August 29	<i>F. typhosa</i> (pure culture)
Urine	August 20	No growth
Urine	August 24	No growth
Urine	August 26	No growth
Duodenal washings	September 13	No growth
Stools (8 specimens)	August 20 to September 10	No enteric pathogens
Stool	September 12	<i>E. typhosa</i>
Stool	September 28	<i>E. typhosa</i>

cytes. The icteric index was 11. Urinalysis was not remarkable except for a slight trace of albumin. The blood Widal reaction was positive in a 1:160 dilution of the serum. The results of cultures are summarized in Table 1.

The diagnoses were acute cholecystitis, generalized arteriosclerosis and obesity.

The patient was treated by bedrest and heat to the abdomen for 15 days before operation was undertaken. During this time, she ran an irregular fever up to 103.6°F by rectum. In general the fever and pulse rate tended to be lower after admission. Nausea and vomiting appeared intermittently. She was given digitalis because of the basal rales and the possibility of heart failure. The right upper-quadrant symptoms persisted, and 1 week after entry a tender mass about 8 by 8 cm. was palpable. The patient was frequently observed by Dr. Reginald Fitz and Dr. John Homans during her hospital stay, and it was their opinion that a perforation of the gall bladder had occurred and that drainage was indicated at that time. However, it was believed that the simplest procedure under local anesthesia should be performed, because the patient was very ill.

Cholecystostomy under local anesthesia was performed by Dr. John Homans on August 15, 1940. A single large gallstone, the size of a ripe olive, was removed. The gall bladder was inflamed and thickened except for one gangrenous area on the anterior medial aspect. Immediately adjacent to that portion of the gall bladder was an abscess walled off by omentum. From the abscess about 30 cc. of thick, greenish-yellow pus was evacuated, from which *E. typhosa* was recovered in pure culture. A catheter was sewed in the gall bladder, and a drain was left in the abscess cavity.

After operation the patient's pulse and temperature

*From the Surgical Service of the Peter Bent Brigham Hospital.
†Assistant in surgery, Harvard Medical School; assistant resident, Peter Bent Brigham Hospital.

showed a downward tendency so that by the 16th post-operative day they were within normal limits. Bile drained in amounts of 100 to 400 cc. daily from the cholecystostomy tube until it was removed on the 15th postoperative day. The drain was taken out 5 days after operation. The stools contained bile at all times, but no bile exuded from the wound after the tube was removed. The wound became secondarily infected in the region of the tube and drain, but otherwise healed quickly. The patient was out of bed 21 days after operation and went home 9 days later. She never became jaundiced, and her general condition was markedly improved at the time of discharge from the hospital.

DISCUSSION

Because of their significance the classic observations of Cushing² in relation to typhoidal cholecystitis and cholelithiasis are repeated here. They are as follows:

(1) The bacilli during the course of typhoidal infection quite constantly invade the gall-bladder; (2) the organisms retain their vitality in this habitat for a long period; (3) in the course of time the bacilli are almost invariably found to be clumped in the bile, suggesting the occurrence of an intravesical agglutinative reaction; (4) these clumps presumably represent nuclei for the deposit of biliary salts, as micro-organisms may with regularity be demonstrated in the centres of recently formed stones; (5) gall-stones being present in association with the latent, long-lived, infective agents, an inflammatory reaction in the viscus of varying intensity may be provoked at any subsequent period.

This patient had her initial attack of cholecystitis only a few weeks subsequent to recovery from typhoid fever in 1897. Four attacks of cholecystitis followed at irregular intervals, but it was not until forty-three years after the attack of typhoid fever that she was subjected to operation. The last attack was undoubtedly the severest, and was a true suppurative cholecystitis, with perforation of the gall bladder and formation of an extravascular abscess. The unabated virulence of the infective agent was demonstrated by the patient's stormy clinical course. It is difficult to describe how critically ill this patient was, but it will suffice to say that experienced observers watched her carefully for two weeks before advising even the simplest operative procedure.

The amazing vitality of the *E. typhosa* was only too well demonstrated here. After a forty-three-year interval, the organisms were recovered in pure culture from the bile, from the pus in the extravascular abscess and from the center of the gallstone. I have not found the report of any case in which *E. typhosa* was recovered from the center of gallstones so long after the original attack of typhoid fever. Whipple³ mentions a case in which he recovered *E. typhosa* from the centers of three gallstones in a patient who had had typhoid fever thirty-two years previously.

Since the gall bladder was not removed in this case, no histologic study was possible. However, Mallory and Lawson⁴ found that seven gall bladders from persons who were known to be typhoid carriers for three months to thirty years all showed evidence of chronic cholecystitis. These workers stated that the constant feature in the gall bladders was a diffuse lymphocytic and plasma-cell infiltration of the mucosa. In addition, there were dense focal collections of lymphocytes in typical lymph-node formation, with hyperplastic germinal centers of immature cells. No organisms could be demonstrated in the wall of any of the gall bladders, and there was no cholesterosis.

The patient in this case raised a large family and did all the cooking, yet she caused no known cases of typhoid fever. Undoubtedly she must have been discharging typhoid organisms in her feces for years, if only intermittently. Unfortunately, no stool cultures were made preoperatively. On ten occasions after the cholecystostomy tube was removed, stool cultures were made; only two were positive for *E. typhosa*. These positive cultures were the last of the series, and were taken fourteen and thirty days respectively after the bile ceased draining through the tube.

Because the patient was a poor operative risk, the gall bladder was not removed. Although drainage and removal of the stone have not cured her of being a typhoid carrier, the gall bladder is now free of a porous foreign body that contained *E. typhosa*, and in time the viscus may become sterile. At any rate, in this case it was probably wiser to have a living typhoid carrier than to risk an operative fatality by cholecystectomy.

SUMMARY

A case of acute suppurative typhoidal cholecystitis and cholelithiasis occurring forty-three years after typhoid fever is reported.

Eberthella typhosa was recovered by culture from the bile, from the center of the gallstone and from the pus in the extravascular abscess. The patient was treated by cholecystostomy and removal of the single gallstone, because she was too poor an operative risk to undergo cholecystectomy. The typhoid organisms were still present in the stools forty-five days after operation.

CLINICAL AND LABORATORY OBSERVATIONS ON HEMOGLOBINURIA OCCURRING DURING SULFANILAMIDE THERAPY*

D. ROURKE GILLIGAN, M.S.,† AND ISRAEL KAPNICK, M.D.‡

BOSTON

ACUTE hemolytic anemia following sulfanilamide therapy is not uncommon^{1,2}. Wood³ has reported an incidence of 24 per cent of acute hemolytic anemia in 378 adults and of 83 per cent in 144 children treated at the Johns Hopkins Hospital. Hemoglobinuria associated with the acute hemolytic anemia has been reported, however, in very few cases. Thus in 21 cases of acute hemolytic anemia following medication with sulfanilamide, Wood³ observed one with hemoglobinuria complicated by gross bleeding from a carcinoma of the bladder, and another in which there was hemoglobin in the plasma but no hemoglobinuria. Kohn⁴ reported a case of hemoglobinuria in a baby, one year of age. Strasser and Singer,⁵ Keefe⁶ and Tavat and Shepard⁶ have each described one case of hemoglobinuria in adults following therapy with this drug.

We have availed ourselves of the opportunity to make clinical observations, hematologic studies and quantitative studies of hemoglobinemia and hemoglobinuria in a case of hemoglobinuria associated with an attack of acute hemolytic anemia during sulfanilamide therapy, which occurred recently in the Beth Israel Hospital. A comparison has been made of the findings in this case with those in some other clinical conditions associated with hemoglobinuria.

CASE REPORT

I R., a 38 year-old Negro chauffeur, entered the hospital on February 5, 1940, with typical signs and symptoms of acute appendicitis. The body temperature was 100°F, the white cell count was 15,500, the spleen and liver were not palpable, the scleras were not icteric, the prostate was enlarged with evidence of prostatitis. X-ray examination of the abdomen by flat plate was negative. There was a history of syphilitic infection 15 years before admission for which some treatment had been received at that time and a history of gonococcal infection 4 years before admission. On two examinations during the present admission the blood Hinton test was positive, the Kahn test doubtful, and the gonococcus complement fixation test positive. Shortly after admission an acutely inflamed appendix was removed under novocain spinal anesthesia. The postoperative course was essentially uneventful until the 4th postoperative day, when the temperature rose to 102°F at noon and remained elevated to 100 or 101.5°F for the

following two days. There were slight redness and induration of the wound. Twenty grains of sulfanilamide and 20 gr. of sodium bicarbonate were administered orally every 4 hours for 2½ days. The dosage of sulfanilamide was then decreased to 60 gr. daily. During these 3½ days of sulfanilamide therapy, the temperature decreased to 99°F (Fig. 1). At the end of this time, that is, on the

FIGURE 1 Relation of Fever, Acute Anemia and Hemoglobinuria to Sulfanilamide Therapy

10th postoperative day, the temperature again increased to 100°F, and a slightly icteric tint of the scleras was noted. The red cell count, which was 4,500,000 on the day after operation, had gradually decreased to 3,500,000 at this time. The blood hemoglobin had decreased from 88 to 72 per cent. The white-cell count was 24,900. Sulfanilamide was omitted. Eighteen hundred cubic centimeters of 10 per cent glucose in physiologic saline solution was given intravenously. Twelve hours later the red-cell count had dropped to 1,400,000, and the hemoglobin to 28 per cent, the scleras had become more icteric, and the temperature had risen to 103°F. The patient complained of no symptoms and said he felt fine; there were no chills, backache or abdominal cramps. At this same time he voided 500 cc of dark, burgundy red, clear urine containing no red cells or casts. The guaiac and benzidine tests were strongly positive. A quantitative study of the hemoglobin of this urine by the benzidine method revealed 460 mg of hemoglobin per 100 cc.

Three transfusions of 500 cc of citrated blood were given in the following 12 hours, the red-cell count increased

*F on the Surg. cal Service and Med. cal Research Laboratory at Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

†Research associate in medicine, Harvard Medical School, medical research associate, Beth Israel Hospital.

‡Surgical house officer, Beth Israel Hospital.

to 2,800,000, the hemoglobin to 54 per cent, and the temperature fell to 99.5°F. The white-cell count was 25,500. The spleen and liver were not palpable. Hemoglobinuria persisted for a total of 18 hours, during which the urine became progressively less red. One and a half days after sulfanilamide had been omitted, the temperature was normal, the plasma was slightly reddish and contained 25 mg. of hemoglobin per 100 cc., and the plasma bilirubin was 1.54 mg. per 100 cc. Urine voided a few hours after this plasma specimen was taken was normal in color and showed no albumin and no hemoglobin. There was no bile in the urine at any time. The following day the plasma was normal in color and contained a normal amount of hemoglobin, namely, 5 mg. per 100 cc. of plasma; the plasma bilirubin was 1.33 mg. per 100 cc.; the red-cell count was 2,800,000 and the blood hemoglobin 62 per cent. Another transfusion of 500 cc. of blood was given, and ferrous sulfate therapy was started. By the 4th day after the apparent onset of the hemolytic attack, the red-cell count was 3,500,000, the blood hemoglobin 70 per cent, the white-cell count 20,600 and the plasma bilirubin 0.3 mg. per 100 cc. The scleras no longer appeared icteric. Further convalescence was uneventful. The patient was discharged to the Out-Patient Department for follow-up study and treatment of syphilis.

The time between the beginning of sulfanilamide therapy and the development of the acute hemolytic attack in this case—namely, three and a half days—accords with the findings of others, who report these attacks as occurring between the third and seventh days of sulfanilamide therapy.^{2, 5} The therapeutic dosage used was not excessive: Keefer⁵ and Long and Bliss² have pointed out that there is no correlation between the size of the therapeutic dose and the development of an acute attack of anemia. On the other hand, certain subjects appear to be particularly susceptible to the development of these attacks, for the same patient has been shown to suffer a recurrence when a second course of the drug was administered.¹

In the case described, hemoglobinuria occurred during the acute attack of hemolytic anemia. Hemoglobin first appeared in the urine about twelve hours after the temperature began to rise and the icteric tint of the scleras was noted; hemoglobinuria lasted eighteen hours and appeared to cease about simultaneously with cessation of blood destruction. In Kohn's³ case hemoglobinuria lasted for twenty-four hours and in Strasser and Singer's⁴ for three days. In our case the urines containing hemoglobin varied from dark Burgundy-red to pink, in Kohn's³ case the urines were pinkish brown and reddish brown, and in Strasser and Singer's⁴ case the urine was described as *bierbraune*.

No enlargement of the spleen and liver was discernible in the case of this study. In the case described by Strasser and Singer⁴ the spleen became palpable, but the liver was not felt. Spleno-

megaly and hepatomegaly are only occasionally found in cases with the acute attacks of hemolytic anemia following the administration of sulfanilamide.^{1, 2} On the other hand, splenomegaly is not uncommon in the slowly progressive type of anemia encountered more frequently with continued therapy using this drug.⁵

The absence in this case of symptoms such as chills, backache and abdominal pain, characteristic of attacks of intravascular hemolysis seen in the syphilitic type of paroxysmal hemoglobinuria and in attacks of hemoglobinuria following transfusion of incompatible blood, is noteworthy. Similarly, in the case described by Strasser and Singer⁴ there were no symptoms except rather severe fatigue. In our case there was a rise in temperature and a marked leukocytosis; in Strasser and Singer's⁴ there was a rise in temperature during the attack. It is to be noted that fever and leukocytosis during sulfanilamide therapy occur in acute attacks of hemolytic anemia unassociated with hemoglobinuria.^{2, 6} Hemoglobinuria, unassociated with symptoms, and in fact in the absence of development of fever, is observed in attacks of march hemoglobinuria,⁸ is frequently observed in the attacks in Marchiafava-Micheli disease^{9, 10} and has been described in a case of massive hemoglobinuria of obscure etiology studied in this laboratory.¹¹

Although acute hemolytic anemia during therapy with sulfanilamide and related drugs is usually not associated with hemoglobinuria, hemoglobinuria following these drugs apparently never occurs except during an attack of acute anemia. The hemolysis which gives rise to the hemoglobinuria and hemoglobinemia is probably only a small part of the total blood destruction occurring during the hemolytic attack. Comparison of the data in the case of the present study with that collected in other studies of hemoglobinuria made in this laboratory^{7, 8, 11} strongly indicates that the amount of hemolysis represented by the circulating hemoglobin in the case of the present study was far too little to explain the rapid development of anemia. For example, the red-cell count decreased in twelve hours from 3,500,000 to 1,400,000, during which 2.3 gm. of hemoglobin was excreted in the urine, whereas in a case of intravascular hemolysis and hemoglobinuria of obscure etiology studied here,¹¹ the red-cell count decreased only from 4,700,000 to 4,200,000 in three days, during which a total of 16 gm. of hemoglobin was excreted in the urine. Similarly, in the case of the present study the plasma-hemoglobin concentration was only 25 mg. per 100 cc. eighteen hours after hemoglobinuria was first noted and was normal the following day, whereas the plasma-hemoglobin in the

other case remained elevated to levels of 500 to 300 mg for the three days discussed. On the basis of previous findings concerning the rate of fall of plasma hemoglobin after a single intravenous injection of a solution of hemoglobin in normal persons,⁷ it can be roughly estimated that the plasma hemoglobin was not greater than 1000 mg per 100 cc at the time of maximum hemoglobinuria, since it had decreased to 25 mg in eighteen hours. This amount in 3000 cc of plasma would be equivalent to only 30 gm of hemoglobin, or the amount of hemoglobin in 190 cc of normal blood. If the plasma hemoglobin did not suddenly reach such a peak and then decrease as after a single injection of hemoglobin in solution into the blood stream, but remained at an appreciably lower level than this peak for several hours during the hemolytic crisis, the amount of hemolysis still would not be essentially different from the value estimated.¹¹ Obviously many times this amount of hemolysis must have occurred to account for the acute development of the severe anemia. These considerations indicate that the mechanism of the development of the acute anemia following sulfanilamide therapy is probably the same in attacks as associated with hemoglobinuria and in attacks in which this manifestation of hemolysis is not present. As suggested by Long and Bliss,² hemoglobinuria in attacks of acute hemolytic anemia following sulfanilamide may occur only in cases with exceptionally rapid hemolysis. A similar situation exists in congenital hemolytic icterus and acute hemolytic anemia (Lederer type), in which hemoglobinuria sometimes occurs in the fulminant hemolytic crises.^{12*}

Because of the presence of syphilis, a Donath-Landsteiner test was performed on the blood of this patient two days after the beginning of the hemolytic attack, and was found to be negative. The red cells were not hemolyzed by the addition of small amounts of hydrochloric acid to the plasma as in the acid hemolysis test,¹⁰ which is diagnostic of cases of Marchiafava-Micheli disease.¹³ No hemolysis occurred on incubation of the patient's washed red cells suspended in physio-

logic saline solution containing sulfanilamide in concentrations ranging from approximately 10 to 50 mg per 100 cc, or on incubation of the washed red cells suspended in the plasma of a patient of the same blood group who was receiving sulfanilamide therapy and had a plasma concentration of free sulfanilamide of 9.3 mg per 100 cc. Tests made several weeks after the hemolytic attack failed to show hemolysis on incubation of the patient's washed red cells suspended in the plasma to which had been added acetylsulfanilamide to give concentrations ranging from approximately 6 to 30 mg per 100 cc.

The treatment of cases developing acute hemolytic anemia during sulfanilamide therapy consists in immediate withdrawal of the drug, forcing of fluids, and repeated transfusions as indicated during the one to three days of the hemolytic attack. The treatment of these cases associated with hemoglobinuria is the same, except that sodium bicarbonate should be administered in sufficient amounts to keep the urine alkaline so that the kidneys may be protected against damage due to deposition of hemoglobin pigment in the tubules.⁵

SUMMARY

A case of hemoglobinuria occurring during an attack of acute hemolytic anemia following sulfanilamide therapy is reported. The hemolytic process was extremely rapid, the red-cell count decreasing from 3,500,000 to 1,400,000 in twelve hours. Hemoglobinuria appeared during the height of the attack and lasted for eighteen hours. There were fever, leukocytosis and jaundice during the attack but no symptoms, the patient insisting that he "felt fine." The hemolytic attack apparently lasted for about twenty-four hours, during which the patient was treated by blood transfusions. Quantitative data on plasma and urine hemoglobin indicate that the hemoglobin that give rise to the hemoglobinemia and hemoglobinuria represented only a very small amount of the total hemolysis.

The mechanism of the development of the acute anemia during sulfanilamide therapy is probably the same in cases without hemoglobinuria as in cases in which this manifestation of hemolysis is present.

* See this manuscript was submitted we have studied another case of hemoglobinuria following sulfanilamide therapy. This patient, a sixty-year-old man, received sulfanilamide in moderate dosage in the treatment of syphilis. Hemoglobinuria began on the sixth day of sulfanilamide therapy and lasted forty hours. As in the case reported in the text, the attack was asymptomatic but there was a rise in body temperature to 102°F and leukocytosis. Jaundice and anemia developed rapidly during the attack. The patient was markedly increased in weight, increased in size, and increased in size. The patient's plasma hemoglobin concentration during the attack was 480 mg per 100 cc. Spectrophotometric examination showed the presence of methemoglobin in the plasma together with oxyhemoglobin. The urine, which was alkaline throughout the attack, contained only oxyhemoglobin. No methemoglobin in hemoglobin casts or hemosiderin. Recovery from the anemia occurred following four blood transfusions and subsequent iron medication.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Special Meeting, April 9, 1941

A SPECIAL meeting of the Council of the Massachusetts Medical Society was held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, April 9. The meeting was called to order at 10:30 a.m. by the president, Dr. Walter G. Phippen, Essex South; 187 councilors were present (Appendix No. 1).

The Secretary *pro tempore* presented the record of the stated meeting of the Council on February 5, 1941, as published in the *New England Journal of Medicine*, issue of February 27. The President declared the record approved as published.

The Council then proceeded to consider the matters for which the meeting was called, namely, reports from the Committee on Medical Education and Medical Diplomas and the Committee to Consider New Officers and By-Laws, copies of which had been forwarded to all councilors on March 26.

Committee on Medical Education and Medical Diplomas

The report (Appendix No. 2) was presented by the chairman, Dr. John P. Monks, Suffolk. At the suggestion of Dr. Monks, the President ruled that Recommendations 1 and 3 be considered first, since they had little to do with the main body of the report, and then Recommendation 9, which was the kernel of the report.

Recommendation 1 was accepted by the Council, and Recommendation 3 was withdrawn by Dr. Monks.

Recommendation 9 was then discussed, sentence by sentence. In regard to (a), Dr. Reginald Fitz, Suffolk, suggested that the sentence in Section 1 of Chapter V relating to "special meetings of the censors" be deleted. After reading (g), Dr. Monks invited discussion concerning the phrase, "has practiced for a minimum of five years," adding

that this was now interpreted by his committee as meaning "five years after graduation." The question as to how graduates of foreign medical schools should be treated was brought up, but discussion was deferred. After the presentation of (o) and (p), Dr. Charles C. Lund, Suffolk, suggested that having different time limits for the receiving of applications of graduates of approved and unapproved schools seemed unnecessarily complicated, and made a motion to amend the changes so that all applications should be received at the earlier date. The motion was seconded and carried.

In the discussion of Recommendation 9 as a whole, Dr. Michael A. Tighe, Middlesex North, asked for information in regard to the admission of graduates of foreign schools, as previously referred to in the presentation of (g). Dr. Monks replied that his committee had had no difficulty in determining the desirability of a physician who was well known in his native country, but that considerable difficulty had been experienced in passing judgment on recent graduates who had come to the United States either of their own volition or as refugees. He added that accurate information collected by the proposed local boards of membership would greatly assist his committee in making its recommendations. Dr. J. Harper Blaisdell, Middlesex East, moved that (g) be amended by adding after the words, "five years," the phrase, "in this state." The motion was seconded and, after considerable discussion, was lost. It was moved and seconded that Recommendation 9 be adopted, with the amendment in regard to dates; it was so voted.

It was subsequently and separately moved, seconded and voted that Recommendations 2, 4, 5, 6 and 7 be adopted.

Dr Monks then inserted Recommendation 7a, which concerned the elimination of the sentence, "Special meetings [of the censors] may be held by order of the Council," in Section 1 of Chapter V, as previously suggested by Dr. Fitz. Its adoption was moved, seconded and approved.

Dr. Monks, at the suggestion of the treasurer, Dr. Charles S. Butler, Suffolk, amended the first sentence of Recommendation 8 to read:

The fee of three dollars shall be paid to the district secretary by an applicant for fellowship for each examination or re-examination by the censors. This shall be sent promptly to the treasurer of the general society for deposit in the funds of the Society

Recommendation 8, as amended, was adopted, as was Recommendation 10.

The last sentence in Recommendation 11 was changed by Dr. Monks, at the suggestion of Dr. Fitz, to read, "It shall revise the list of medical schools and colleges recognized by the Council annually, for approval by the Council." Recommendation 11, as amended, was adopted.

The changes covering the readmission of former members of the Society—Recommendations 12, 13 and 14—were adopted without discussion.

After commending Dr. Monks's committee, and Dr. Monks in particular, for a very able piece of work, the President asked for a motion to accept the recommendations as a whole. This was made and seconded, and was so voted.

Committee to Study New Officers and By-Laws

The report (Appendix No 3) was presented by the chairman, Dr. John Homans, Suffolk. He stated that the committee had attempted to get in touch with all the district societies to obtain their ideas in regard to the proposed executive committee of the Council. The consensus was that such a committee should be composed of a representative from each district. Dr. Homans then suggested, with the approval of the President, that the Council consider the changes proposed in Chapters III, IV and VI relative to the creation of an executive committee.

The additions to Sections 5 and 7 of Chapter III, having to do with the election of the member of the Executive Committee by the councilors of each district, were then considered. Some discussion arose concerning the word, "immediately," and it was finally voted to amend both sections by substituting "at or as soon as possible" for the word. The additions were adopted, as amended.

Section 10, an addition to Chapter IV, was then discussed. Dr. Homans said that in the second

paragraph the word, "immediately," should be replaced by "at or as soon as possible," as was done in Sections 5 and 7 of Chapter III. The President stated that the last sentence in the first paragraph was unnecessary, and it was voted that the sentence be deleted. Dr. Monks suggested that "1941" in the first sentence of the second paragraph be replaced by "the first year of operation," the change being accepted by Dr. Homans and the President. The new section, as amended, was adopted.

The addition to Section 1 of Chapter VI was adopted, as were the recommendations, as a whole, dealing with the Executive Committee.

Dr. Homans then proceeded with the proposed changes necessitated by the appointment of an executive secretary. He said that the changes in Section 4 of Chapter VI merely define what the secretary of the Society must do and what he may assign to an executive secretary. It was pointed out that the first sentence in the eighth paragraph was a repetition of the second paragraph; the deletion of this sentence was accepted. In the discussion of Section 5 of Chapter VI, it was suggested that, in the first paragraph, "shall" be replaced by "may" in the first sentence, and "until his successor has been duly elected" be replaced by "at the pleasure of the Executive Committee" in the second. (Subsequent to the meeting, the first sentence was shifted and substituted for the fifth paragraph of Section 10 of Chapter IV, where it obviously belonged.) In commenting on the suggested changes, the President called attention to the fact that they merely permitted the Executive Committee to choose an executive secretary if it saw fit or if it were so instructed by the Council. The changes, as amended, were adopted. The President ruled that the proposed change in Section 1 of Chapter V did not require action.

The Council then adopted the recommendations of the committee as a whole.

It was moved, seconded and voted that the thanks of the Council be extended to Dr. Homans and his committee and that the committee be discharged from further duty.

Incidental Business

The President then attempted to carry out certain routine business of the Society. Dr. Braintree F. Conley, Middlesex South, raised the question whether this could be done, since the meeting had been called for a special purpose. The President ruled that such matters could be considered, but asked for opinions from ex-presidents of the Society. Dr. Channing Frothingham, Suffolk, and Dr. Walter P. Bowers, Worcester, concurred.

whereas Dr. Halbert G. Stetson, Franklin, and Dr. Charles E. Mongan, Middlesex South, dissented. Dr. Elmer S. Bagnall, Essex North, moved that the Council endorse the President's interpretation; this motion was seconded and carried.

Three restorations to fellowship (Appendix No. 4) were authorized by the Council, and new committees to consider the restoration of eleven former fellows (Appendix No. 5) were nominated by the President and approved by the Council. With the latter, Dr. Monks suggested that the committees be instructed to report to the Council at the May meeting, owing to the proposed changes in the by-laws; the President instructed the Secretary to notify the committees accordingly.

The appointment of Dr. Edwin D. Gardner, of New Bedford, to replace Dr. Ralph W. French, of Fall River, as a delegate to the annual meeting of the Rhode Island Medical Society was confirmed.

An increase in the Committee on Maternal Welfare from ten to fifteen members was authorized by the Council.

A letter from Mr. William W. McCarthy, of the National Shawmut Bank, relative to means of financing the costs of medical care, was referred to the Committee on Public Relations.

Dr. Fitz, as chairman of the Committee on Medical Preparedness, presented a resolution covering the deferment of medical students and interns (Appendix No. 6). This was adopted by the Council.

Dr. Bagnall presented a motion stating that each district representative on the Committee on Public Relations should be a councilor and also the chairman of the public-relations committee in his district society. The President stated that the Council had no power to pass such a rule, since the selection of local officers rests entirely in the hands of the members of the district society, but that it might be acted on as a sense-of-the-meeting matter. It was so moved and seconded, and the motion was passed.

Dr. William A. R. Chapin, Hampden, asked for information in regard to what should be done by the medical profession to counteract the ruling recently obtained by the federal government in its suit against the American Medical Association and certain subsidiary organizations. Dr. Tighe, by permission of the President, replied that the decision would be appealed and that no action should be taken until the matter was finally settled in the courts.

The meeting was adjourned at 1:32 p.m.

ROBERT N. NYE, *Secretary pro tempore*.

of the committee is solely responsible have been inserted after each suggested change in the by laws

For several years among the applicants for fellowship in the Society the number of graduates of medical institutions not on the list recognized by the Council has been increasing. At present there are two groups of such graduates. One, and much the larger group, is composed chiefly of graduates of domestic institutions not recognized as medical schools by the American Medical Association. This group also includes a few American born graduates of foreign medical schools who have studied abroad usually because they were not accepted by any recognized domestic medical school. There are a few foreign born, foreign educated physicians in this group who have migrated to this country, chiefly before 1937. The other group, much smaller than the first, is composed almost entirely of foreign born graduates of foreign medical schools who are chiefly German and Jewish, but by no means exclusively either. Most of these physicians have migrated recently to this country, primarily to escape political oppression. Almost without exception they have had a good medical education and are of proved ability, often being older men of outstanding ability with international reputations.

The members of the Committee on Medical Education and Medical Diplomas are unanimous in believing that it is in the best interests of this Society to treat these two groups differently. The basis of this difference we believe should be whether or not an applicant has had an adequate medical education and enjoys a good professional reputation. With very few exceptions the members of the first group have had an inadequate education, those of the second an adequate one, and it is usually not difficult to distinguish between them. We believe that members of the first group should be admitted to membership only when there is ample positive proof that they can be regarded as truly desirable additions to the Society. At present, in the absence of evidences of undesirability other than an inadequate medical education they are assumed to be desirable. We cannot agree with this attitude. We believe the members of the second group should become members of the Society as soon as they have been long enough in this country to have created definite favorable opinion in the minds of colleagues whose judgment would be commonly considered valuable.

The committee has been unable under the present system to evaluate adequately the desirability for fellowship of the majority of candidates appearing before it. Repeated attempts to gather information about the prospective candidates from the officers and fellows of the district societies have usually failed. A typical situation is for an applicant who is a graduate of an unrecognized domestic school to appear before the members of the committee, who have never seen him before but who must decide as to his desirability from his appearance, diploma, application blank and a sheaf of letters personally solicited from his medical acquaintances who invariably say that the applicant is a capable and conscientious practitioner of medicine and that his practice is ethical. Only rarely has the committee received what it regards as a confidential expression of honest intelligent opinion regarding an applicant and his work from colleagues who really know him. Part of the present functioning of the committee as dictated by the by laws has become farcical in the minds of its members. A major change in this undesirable situation seems impossible under the present by laws.

APPENDIX NO 2

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION
AND MEDICAL DIPLOMAS

The Council at its meeting May 21, 1940, directed the Committee on Medical Education and Medical Diplomas to submit to it changes in the by laws relative to the method of admission of the graduates of unapproved medical schools to the Society. While engaged in this task the committee thought that certain other matters not directly in line with the above purpose, but more or less related to it should be included in the changes to be submitted. Following are the report and recommendations as submitted to the Council at its meeting on February 5, 1941. It was decided at that meeting that the report should be printed in full with appropriate comments, so that the whole matter might be more carefully considered at a special meeting of the Council to be called for that purpose. Explanatory comments for which the chairman

The committee therefore recommends that the following changes be made in the by-laws:

1. The name of the committee be changed to the Committee on Medical Education. (*The Committee on Medical Diplomas was created in 1881 primarily to make a periodic revision of the list of medical schools recognized by the Council. The Committee on Medical Education was created in 1906 primarily to consider improvement of state laws regarding registration in medicine. The two committees were combined in 1913. The present chief function of the Committee on Medical Education and Medical Diplomas is to investigate the qualifications of applicants who are graduates of unrecognized schools. The change is recommended only in the interest of simplification.*)

2. Chapter I, Section 1: In line 5 on page 9 delete the clause, "that their names and addresses . . . prior to their examination by the censors." (*This clause appears more appropriately elsewhere. See Recommendation 9.*)

3. In line 10 on page 9 omit the words, "or college." (*It seems unnecessary now to use the terminology "medical school or college," though it once might have had some legal reason. The change is recommended only in the interest of simplification.*)

4. In line 14 on page 9 after "code of ethics of this Society;" insert "that they have made application according to the provisions of Chapter V, Section 2; that they have paid the examination fee of three dollars." (*The ultimate responsibility of seeing that all new applicants comply with the various provisions for entrance into the Society should rest with the censors. Article 3 of the constitution of the Society reads in part as follows, "No person shall become a member of the Massachusetts Medical Society except upon examination by the censors of said society . . ." The contents of these two clauses are discussed under Recommendations 9 and 8a respectively.*)

5. Chapter I, Section 6: In line 5 on page 10 substitute the word, "December," for "November." (*The date of the present fall censors' examination is the first Thursday in November. According to the new "time-table" set up under Recommendation 9 the first Thursday in December seems better, as otherwise the closing date for applications from graduates of unapproved schools falls too close to Labor Day, an admittedly poor date for district secretaries and applicants alike. No such change in the date of the spring examination is needed.*)

6. Chapter V, Section 1: Beginning at line 11 from bottom of page 16, delete the whole paragraph, "Diplomas from medical schools . . . to take an examination." (*The contents of this paragraph appear more appropriately elsewhere. See Recommendation 9. The only factual change is in the period of time.*)

7. In line 2 from bottom of page 16 substitute the word, "December," for "November." (*See Recommendation 5.*)

8. At the bottom of page 16 insert the following: (a) "A fee of three dollars shall be paid by an applicant for fellowship to the district secretary for deposit in the funds of the general Society before each examination or re-examination by the censors. (b) An applicant shall not be considered as possessing the requisite qualifications for fellowship unless approved by at least three censors. (c) An applicant failing two examinations shall be disqualified from again applying for fellowship until three years have elapsed from the date of the last application."

(a. Examination by the censors of applicants for fellowship at present involves the applicant in no expense. The

censors, however, are paid for their work, as provided for in Chapter V, Section 4, of the by-laws. In accordance with the usual custom of institutions of learning, learned societies and boards of registration in medicine everywhere it is felt that the Society should charge a fee for its examinations.

b. Unchanged.

c. If an applicant is not passed by the censors at two examinations, it is believed that some time should elapse before re-examination, so that an applicant may improve his qualifications and not appear at every examination with essentially unchanged qualifications.)

9. Chapter V, Section 2: To read as follows:

(a) "An applicant for fellowship who is a graduate of a medical school recognized by the Council shall apply on a form furnished for the purpose to the secretary of the district in which he has legal residence, not later than March 1 for the May censors' examination or October 1 for the December censors' examination. (b) At this time the district secretary shall verify the applicant's diploma and shall deliver the application form to the Secretary of the Society not later than March 10 or October 10 respectively. (c) An applicant nonresident in Massachusetts shall apply to the secretary of the Suffolk District Medical Society and shall be examined by the censors thereof. (d) Consideration of a late application shall be postponed until before the next succeeding examination. (e) The names of all such applicants, their addresses, medical schools, dates of graduation and the names and addresses of the various district secretaries shall be published in a list in the first number of the *New England Journal of Medicine* on or after April 1 or November 1. (f) Confidential communications regarding the qualifications of applicants for fellowship shall be requested of the fellows of the Society to be sent to the appropriate district secretary not later than April 15 or November 15.

(g) "An applicant for fellowship who is a graduate of a foreign medical school or a domestic medical school not on the list recognized by the Council or of a medical school no longer in existence, and who has practiced for a minimum of five years, shall apply for fellowship in like manner with the following exceptions and additions:

(h) "The application form must be submitted to the district secretary not later than February 15 or September 15. (i) At this time also the applicant must submit the name and address of a fellow of the Society who has agreed to act as his sponsor. (j) The sponsor's duty is to obtain from fellows of the Society who are acquainted with the applicant and his work, confidential written opinions regarding his qualifications for fellowship to be mailed directly to the district secretary not later than March 15 or October 15. (k) The application form of such an applicant shall be delivered by the district secretary to the Secretary of the Society not later than February 20 or September 20. (l) A list, similar to that of applicants who are graduates of recognized schools, but with the addition of names and addresses of sponsors shall be published in the first number of the *New England Journal of Medicine* on or after March 5 or October 5.

(m) "The president, secretary and supervising censor of the district society, sitting as a local board of membership, shall then gather such further information as is deemed necessary to determine whether an applicant is a capable and conscientious practitioner of medicine and possesses a good professional reputation among his col-

leagues (n) Every candidate must be personally interviewed by this board

(o) The district secretary shall deliver to the chairman of the Committee on Medical Education a complete confidential file of all applications including correspondence, and the written recommendations of the local board with supporting reasons for advocating the acceptance or refusal of each applicant not later than April 1 or November 1

(p) The committee shall then determine whether or not each candidate shall be approved for examination by the censors, and shall notify the district secretary and each applicant of their decision not later than April 20 or November 20

(a) *Provisions unchanged except for dates* The system of definite unchanging dates from year to year is utilized throughout except in the case of examination dates, rather than the present method of dating by giving the number of weeks before the examination. The present method has always caused confusion in the minds of district secretaries and applicants alike since the actual date differs each year. Dates are set so to allow ample time for the district secretaries, the secretary of the Society, the editor of the Journal, the local boards of membership and the Committee on Medical Education to perform their duties properly, as well as to allow no misunderstanding in anyone's mind concerning the date by which certain duties should be finished. Anyone who has not been one of the above mentioned officers has difficulty in appreciating the importance of this point

b *Transporting bulky framed diplomas to be shown to more than one official of the Society, as now occurs is unnecessary* The Secretary of the Society has to certify and edit certain information on the application blanks before publication in the Journal

c *Unchanged*

d *Nothing is more troublesome to all the officials concerned than attempting to handle late applications which now are submitted up to the very eve of the examination and which are always coupled with requests for special consideration*

e *Unchanged except as to dates*

f *Occasionally unfavorable information of importance about an applicant exists. If it is withheld by an applicant's colleagues and an applicant is omitted to the Society responsibility should rest on those who withheld the information. Such information when made available is always treated confidentially*

g *Unchanged in essentials*

h *The difference in dates from those in a is due to the more numerous procedures required in the cases of graduates of unapproved schools*

i and j *Sponsorship of an applicant who is a graduate of an unapproved school is a new proposal. Previously the applicant always personally approached his colleagues and asked for written recommendations. This system produced recommendations some of which were retracted by their writers in separate communications and other recommendations which were obviously written by fellows who were only casually acquainted with the applicant and others which were refuted by other available information. It is hoped that the new system will alleviate the embarrassment of an applicant's personally asking for a recommendation from a fellow who does not feel he can honestly give it*

k *See b*

l *Unchanged, except as to dates*

m *This change is the most fundamental of all those suggested. The Committee on Medical Education and*

Medical Diplomas has sensed for a long time how helpless it was in obtaining adequate information on which to determine the desirability of candidates for fellowship, this point has already been discussed more fully in the formal report. It is believed that a local board will be in every way better fitted to obtain this information than the central committee. The number of men on the board is small, they are already in positions of responsibility in their local society, and two of the three are already members of the board of censors which eventually will examine those candidates finally approved. Further, it is very definitely felt that in the case of graduates of unrecognized schools the essential responsibility of whether or not they should be admitted to membership in the local society should be with their own nearby colleagues, not with those farther afield. See Recommendation 11 e

n *Unchanged except that the interview shall be carried out by the local board rather than the central committee*

o and p *This provides that the central committee shall take the responsibility of seeing that on one hand undue pressure has not been brought to bear on the local board to recommend for approval an undesirable applicant nor on the other hand has unwarranted local prejudice bordered from approval a desirable applicant*

10 *Chapter V, Section 3* In line 4 on page 17 after the words, 'applicants for fellowship,' insert the clause 'they shall see that each applicant pays the examination fee' (See Recommendation 8 a. This is inserted as it becomes a new duty for the district secretary)

11 *Chapter VII Section 5* First two paragraphs to be changed to read as follows

(a) "The Committee on Medical Education shall consist of five fellows. It shall consider all matters relating to medical education which may be referred to it by the Council." (b) It shall review the case of every applicant for fellowship who presents according to the provisions of Chapter V, Section 2, a diploma from a medical school not on the list recognized by the Council. (c) It shall have the power to approve for examination by the censors such an applicant and all decisions of the committee thereon shall be final. (d) It shall revise the list of medical schools recognized by the Council whenever it appears necessary."

(a) *Unchanged*

b *Changed in accordance with 9 a and p*

c *Unchanged*

d *Changed in that previously the committee had to await direction by the Council to accomplish this duty. It is believed that this list should conform to that of the medical schools approved by the American Medical Association which is changed from time to time. The present list dated 1934 needs sixteen changes to bring it into such conformity.*

A recent ruling by the President reversed the previous interpretation of the provisions of the bylaws regarding the application for readmission to the Society of a former fellow whose resignation had been requested by the Committee on Ethics and Discipline. Inasmuch as the individual in question was a graduate of an unrecognized school, it was ruled that he had to appear before the Committee on Medical Education and Medical Diplomas for approval, before being allowed to appear before the censors. Due to information requested from the chairman of the Committee on Ethics and Discipline, the Committee on Medical Education and Medical Diplomas disapproved the application. The latter committee, as a result of this case, believes that it should have no jurisdiction in such cases.

of readmission to the Society, and as a result studied the provisions of the by-laws regarding readmission. With the approval of the Committee on Ethics and Discipline and the Committee on Membership it recommends that the following changes be made in the by-laws:

12. *Chapter 1, Section 7:* To read as follows: "The resignations of fellows whose assessments have been paid in full or remitted may, on recommendation of the Committee on Membership, be accepted by the Council and sent to the treasurer of the Society." (*The sentence dealing with readmission is deleted. The matter is now dealt with in Recommendation 14 a.*)

13. *Chapter 1, Section 8:* Omit last paragraph, "Fellows who have been deprived . . . secretary of the general Society." (*The sentences dealing with restoration to fellowship are deleted. The matter is now dealt with in Recommendations 14 a, b, c, d, and e.*)

14. *Chapter 1:* Add *Section 10*, to read as follows:

(a) "Former fellows who desire to be readmitted to the Society shall make application in writing addressed to the Council and sent to the secretary of the Society. (b) Such applications shall be referred for investigation and personal interview to the local boards of membership, which shall report their recommendations to the Committee on Membership. (c) The committee shall render the final decision as to whether to recommend to the Council the readmission of former fellows. (d) The Council shall have the power to readmit former fellows so recommended. (e) Boards having under consideration the applications of fellows whose resignations have been requested by the Committee on Ethics and Discipline, or who have been deprived of fellowship under the terms of section 8, clause (c), shall consult with the Committee on Ethics and Discipline before reporting their recommendations."

(a and b. *The distinction formerly made in Chapter 1, Sections 7 and 8, between the method used in readmitting to fellowship those fellows who having "resigned" and those who having been "deprived of the privileges of fellowship" desire to rejoin the Society has been eliminated. It is believed that the local boards of membership can more adequately investigate the facts surrounding a fellow's separation from the Society and the altered situation that leads him to seek readmission than can either the censors or a specially appointed committee, as is the practice at the present.*

c. *The Committee on Membership should retain jurisdiction to review the recommendations of the local boards as it does at present in all cases of deprivation of fellowship. At the present it has no jurisdiction in cases of readmission to the Society following resignation.*

d. *The Council should have the full power of readmission of all former fellows recommended by the Committee on Membership. At present it has no jurisdiction in cases of readmission to the Society following resignation.*

e. *At present in cases where the Committee on Ethics and Discipline has requested a fellow's resignation as a form of discipline, and such resignation has been received, and the fellow later reapplies for readmission, the Committee on Ethics and Discipline has no jurisdiction in the matter of readmission. If the fellow in question is a graduate of an unrecognized school he must appear at present before the members of the Committee on Medical Education and Medical Diplomas, who if they approve his application pass him on to the censors for examination. This procedure is most illogical, since those who know nothing about the fellow deal with his readmission, while*

those who know everything about him have no official hand in the matter. At present the Council acting on separate reports of the Committee on Ethics and Discipline and the Committee on Membership may deprive a fellow of the privileges of fellowship as provided in Chapter 1, Section 8 (c). With such a fellow desiring restoration to fellowship, a special committee is appointed to consider his case, and the by-laws provide that this committee must include at least one member of the Committee on Ethics and Discipline. The latter committee believes that with the institution of local boards of membership consultation with the Committee on Ethics and Discipline will provide sufficient opportunity for the board to know all the facts in the case before reporting its recommendations.)

JOHN P. MONKS, Chairman.

APPENDIX NO. 3

REPORT OF THE COMMITTEE TO CONSIDER NEW OFFICERS AND BY-LAWS

Following the Council meeting of October 2, 1940, a committee was appointed by the president of the Massachusetts Medical Society to study the desirability of establishing the offices of president-elect and full-time or executive secretary and to suggest the necessary changes in the by-laws required to create these positions. At the Council meeting of February 5, 1941, the by-laws dealing with the creation of the office of president-elect were accepted. At the same meeting the plan of having an executive secretary was accepted in principle, but the manner of electing the executive secretary was left to be determined.

At the Council meeting of October 2, 1940, a motion was made that this same committee should study the possibility of redistricting the Massachusetts Medical Society, with the idea of harmonizing its set-up with that of the American Medical Association and other state societies. The committee, in reporting at the Council meeting of February 5, 1941, took no action in respect to the problem of redistricting, but did suggest certain by-laws by which an executive committee of the Council could be established. In respect to the latter, the Council voted "that the committee continue and that it explore the possibilities of an executive committee so constituted that each district medical society would be represented."

Hence, your chairman has circularized the secretaries of the different district societies, asking them to secure, if possible, in the brief time between Council meetings, an opinion from their respective districts as to the best method of selecting an executive committee of the Council, and the possibility of redistricting the Massachusetts Medical Society.

In one way or another, your chairman has heard from six secretaries and from various sources has received the following impression: that no district desires a change in its boundaries and that a majority of the districts are opposed to such a change; that the idea of an executive committee of the Council is generally acceptable and that the districts prefer that each of them should be represented on this committee, no others to be made members of the committee except the officers of the Society. In accordance with this understanding, your committee, after consulting together, suggests the following changes in the by-laws.

JOHN HOMANS, Chairman.

CHAPTER III

DISTRICT SOCIETIES

Section 5 (Additional)

The councilors of each district society shall meet immediately after the annual meeting of the district society in 1941 and elect one of their number to serve as a member of the Executive Committee of the Council in accordance with Chapter IV, Section 10. Thereafter, in a similar manner, they shall elect a new member from time to time.

Section 7 (Additional)

The secretary of each district society immediately after the annual meeting of the district society in 1941 shall call together its councilors for the purpose of electing a member of the Executive Committee of the Council and shall send the name of the member chosen to the Secretary of the general Society. He shall see that a new member is chosen in a similar manner to fill a vacancy as it occurs, in accordance with Chapter IV, Section 10.

CHAPTER IV

THE COUNCIL

Section 10 The Executive Committee shall consist of the President, President Elect, Vice President, Secretary and Treasurer *ex officio*, and a councilor from each district medical society chosen in accordance with Chapter III, Section 5. The election of a councilor to the Executive Committee of the Council shall not be considered as leaving a vacancy among the councilors from the district he represents.

The councilors of each district society shall meet immediately after its annual meeting in 1941, as specified in Chapter III, Section 5, and in a similar manner at stated intervals as specified below, to choose one of their number to serve as a member of the Executive Committee of the Council.

A member of the Executive Committee shall serve for three years and shall not be eligible for re-election before the expiration of three years following the conclusion of his term of office, except that in 1941 six members shall be selected by lot to serve one year, six members shall be selected by lot to serve two years and six members shall be selected by lot to serve three years. Thereafter, six members shall be elected every year to succeed in office those whose terms are about to expire.

The Executive Committee shall meet at the call of the President at least once in each interval between Council meetings and may meet more often at the pleasure of the President. It shall assist the President in preparing for the consideration of the Council matters calling for action by the Council at its next meeting. It shall authorize action by the officers of the Society when circumstances require it, subject to the approval of the Council. It shall perform such other duties as the Council may require.

The consent of the Executive Committee shall be required to confirm the appointment, upon nomination by the President, of the Executive Secretary of the Society.

Upon request, members of the Executive Committee shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER V

CENSORS AND SUPERVISORS

Section 1 The supervisors, representing the censors of the several district societies, shall constitute a board, which shall meet annually on the day appointed for the annual meeting of the Council. The board shall elect a

chairman, who shall have power to call special meetings. Five supervisors shall constitute a quorum. The Secretary or Executive Secretary of the general Society shall act as secretary of the board. He shall call special meetings at the request of five supervisors. He shall keep a permanent record of the proceedings of the board, and shall provide, at the expense of the Society, papers and forms necessary for conducting examinations of applicants for fellowship. The board at its annual meeting shall adopt a uniform plan for the examination of applicants. The supervisors shall be paid the amount of their traveling expenses from the funds of the Society.

CHAPTER VI

OFFICERS

Section 1 (Additional)

He shall call at least one meeting of the Executive Committee of the Council between Council meetings and may call more meetings if he so desires.

Section 4 The Secretary may assign to an Executive Secretary any or all the duties now to be enumerated, except as specified below.

The Secretary shall attend all meetings of the Society and of the Council, and shall record their respective proceedings in separate record books, and this duty he may not assign.

He shall cause to be engrossed and shall sign the diplomas of new fellows if satisfied that they have met the requirements of Sections 1 and 2 of Chapter I, and shall issue all diplomas and certificates of fellowship. He shall notify individual fellows, in appropriate instances, of votes by the Council granting permission, as the case may be, to retire, to resign, to change district membership, to have dues remitted, or of votes depriving them of the privileges of fellowship, and these duties he may not assign.

He shall act *ex officio* as secretary of all boards of trial and this duty he may not assign.

He shall have custody of the seal of the Society and of all books, papers, manuscripts, prints and paintings belonging to the Society, except such as are in charge of the Treasurer, and this duty he may not assign.

He shall act *ex officio* as secretary of the Board of Supervisors and of the Committee on Publications and the Committee on Ethics and Discipline, and shall keep the records of each in a separate volume. He shall have custody of all records as thus kept.

He shall issue notices of the meetings of the Council. One month before the annual meeting of the Society, he shall issue to every fellow a program, which shall contain notification of the time and place of the annual meeting, notification of the stated meetings of the Council for the year and the meetings of the boards of censors, and information concerning the payment of assessments and the distribution of publications.

He shall record the Proceedings of the Council and of the Society. He shall keep a complete list of the fellows of the Society, with their addresses so far as known. He shall transfer fellows from one district to another under the terms of Chapter III, Section 2, and shall report to the Society at its annual meeting the changes in membership of the Society during the year.

He shall conduct the official correspondence of the Society, and shall notify officers, delegates and members of the committees of the general Society of their appointments and of their duties.

Under the direction of the Committee on Publications he shall issue at such intervals as may be determined by

the Council a directory of officers and fellows of the Society, which shall be furnished upon request to fellows who are not in arrears.

He shall perform such other duties as the Society or the Council may require.

Section 5. An Executive Secretary shall be chosen by the Executive Committee of the Council upon nomination by the President. He shall hold office until his successor has been duly elected.

He shall perform such duties as are assigned to him in Section 4 of this chapter and by the Executive Committee. In general, he shall assist the officers of the Society and such standing and other committees as may request his services, and the Society shall have the first call upon his services.

He shall attend all meetings of the Council and, on request, attend the meetings of the Executive Committee of the Council, but shall not vote in either.

An Executive Secretary need not be a physician.

APPENDIX NO. 4

REPORTS OF COMMITTEES TO CONSIDER PETITIONS FOR RESTORATION TO THE PRIVILEGES OF FELLOWSHIP

Restoration to fellowship, with the usual provision regarding payment of dues, was recommended for the following three former members:

Julian C. Gant, Arlington (Committee: Edwin P. Stickney, Letitia D. Adams and Alfred Weller).

Charles H. Hogan, Salem (Committee: Charles L. Curtis, Thomas F. Henry and Stuart N. Gardner).

Arthur J. Taveira, New Bedford (Committee: Frank M. Howes, Edwin D. Gardner and Curtis C. Tripp).

APPENDIX NO. 5

COMMITTEES APPOINTED TO CONSIDER APPLICATIONS FOR RESTORATION TO FELLOWSHIP

The following committees were appointed to consider the petitions for restoration to fellowship of the following eleven former members:

For Bernard H. Appel, Brighton:

Max Ritvo, David Stern and Robert H. Aldrich.

For Harold I. Cohen, Lynn:

Charles F. Twomey, Bernard Appel and Charles L. Hoitt.

For Frederick E. Cruff, Norwell:

Bradford H. Peirce, Roy F. Littlehale and Charles Hammond.

For J. Frank Curtin, North Abington:

Joseph H. Dunn, John M. Peckham and Jonah Fieldman.

For Leroy S. Ford, Keene, New Hampshire:

Samuel N. Vose, Hollis L. Albright and Walter H. Lacey.

For Maurice Gerstein, Brookline:

Charles J. Kickham, Edward L. Kickham and Albert Ehrenfried.

For Elihu I. Lewis, Boston:

William T. O'Halloran, Mark D. Altschule and Nathan L. Fineberg.

For Coval H. Liverpool, West Somerville:

Charles W. Finnerty, John E. Gillis and Herbert Cholerton.

For John L. O'Toole, Haverhill:

William W. Perrin, Lucien R. Chaput and George J. Connor.

For Nathan Silverman, Lawrence:

John J. Deacy, John J. Kelleher, Jr., and Joseph A. Levek.

For Thomas V. Uniack, Lawrence:

Roy V. Baketel, Victor A. Reed and Henry F. Dearborn.

APPENDIX NO. 6

RESOLUTION PRESENTED BY THE COMMITTEE ON MEDICAL PREPAREDNESS

WHEREAS, The regulations of the Selective Service Act provide against deferment for military training of particular groups of persons; and

WHEREAS, These regulations provide for individual deferment of persons in any capacity deemed necessary for the national health, safety or interest, thus enhancing the efficiency of such individuals for a particular type of such needed service; and

WHEREAS, Physicians play an indispensable part in both the civilian and military aspects of the national defense program; and

WHEREAS, The needs for competently trained physicians will be greatly extended to meet both the civilian and military requirements of the present emergency; and

WHEREAS, A period of four years of intensive continuous training is required after a man enters a medical school and thereafter at least one year of hospital experience as an intern before he can be developed into a physician of any competence; and

WHEREAS, The Council of the Massachusetts Medical Society here records as its considered opinion that the future health needs and proper medical care of the nation and of the defense forces demand that there be no interruption in the stream of adequately trained physicians entering the ranks of the profession from medical schools and hospitals; therefore, be it

RESOLVED, That the Council and members of the Massachusetts Medical Society urge local and appeal selective-service boards in Massachusetts to give due and proper consideration to the medical needs of their respective communities when considering physicians for military service, to the end that the citizens of rural sections and small towns be not deprived of necessary health and medical services; and be it further

RESOLVED, That, to ensure a continuing supply of adequately trained physicians to meet the nation's medical needs of the future, the Council and members of the Massachusetts Medical Society urge local and appeal selective-service boards carefully and sympathetically to consider semiannual deferments on an individual basis, as provided in selective-service regulations, of students in recognized schools for medical teaching and of interns in hospitals until the completion of at least one year's internship; and be it further

RESOLVED, That copies of this resolution be sent to the Governor of the Commonwealth of Massachusetts, to directors of the federal and state selective-service system, and to the chairmen and members of all local and appeal selective-service boards within the Commonwealth.

REGINALD FITZ, *Chairman.*

MEDICAL PROGRESS

BACTERIOLOGY*

The Significance of Bacteriologic and Immunologic Procedures in the Diagnosis and Treatment of Infections

CHARLES A. JANEWAY, M.D.†

BOSTON

WITH the development of powerful and specific agents for the treatment of infections, accurate diagnosis has become increasingly important. It is extremely difficult to handle a patient in diabetic coma without the aid of a chemical laboratory, and it is equally impossible to give satisfactory care to patients with serious infections without the assistance of a good bacteriologic laboratory. Consequently, the efforts of the Massachusetts Department of Public Health to improve the quality of bacteriologic work throughout the Commonwealth by a system of inspection and approval of laboratories is commended. With these considerations in mind, I shall discuss the present status of diagnostic procedures from the point of view of both the clinician and the laboratory man.

BACTERIOLOGIC PROCEDURES

Smears

With the refinement of laboratory methods, older and simpler tests are often forgotten. This has been true of the practice of examining stained smears of bacteriologic material. As a method of exact diagnosis, a smear has great limitations, but as a guide to the clinician and bacteriologist, it is of inestimable value. It gives a tentative indication of the type of infection in a few minutes, whereas cultures take at least eighteen hours, and it shows the proportions of various types of organisms in mixed infections, as well as the cellular reaction in the exudate.

Smears are particularly useful in the examination of exudates from sites normally sterile, such as serous cavities, the subarachnoid space and tissues. The importance of smear examination in cases of peritonitis and empyema cannot be over-emphasized, for cultures from these cases often fail to grow. A discussion of the valuable information yielded by smears of abdominal fluid obtained at laparotomy has recently been published.¹

Smears made from sites at which there are normally profuse bacterial flora are difficult to inter-

pret and usually fall to the lot of the medical man. Throat smears are extremely unreliable in the diagnosis of diphtheria and various forms of tonsillitis, and the physician should be guided by his clinical judgment from the appearance of the lesion and by properly taken cultures for confirmation. In pneumonia, the gross inspection of the sputum, in conjunction with examination of a stained smear, may yield valuable information, particularly in such unusual cases as Friedländer's pneumonia. In venereal diseases, smears may be very useful from a man, who normally has an almost sterile urethra, whereas those from the female cervix mean little unless frank pus is seen. Smears of urinary sediment are often more valuable than cultures, when the latter are done by simple broth inoculation. Perhaps the greatest use for smears in medical conditions is in examination of fluid aspirated from acutely inflamed joints, and of cerebrospinal fluid.

Certain pitfalls in smear examination are not commonly appreciated. All the gram-positive cocci—staphylococcus, pneumococcus and hemolytic streptococcus—tend to assume a diplococcal form when growing rapidly in the body, so that the finding of diplococci or short chains is not pathognomonic of a particular coccus, and one must accordingly be somewhat cautious in interpretation until cultures are made. Moreover, virulent hemolytic streptococci form capsules in rapidly spreading infections. In a case of peritonitis, recently observed, a smear showed gram-positive diplococci. These were taken to be pneumococci, and a Neufeld test was set up with Type 1 anti-pneumococcus serum. This showed large, apparently swollen capsules and was called positive. On the next day, culture revealed a pure growth of beta-hemolytic streptococcus, much to the bacteriologist's surprise.

Smears of the cerebrospinal fluid in meningitis may be quite confusing unless the physician is on his guard. The gram-positive cocci can be quite readily seen, but gram-negative meningococci may be very difficult to find. In children, meningitis due to the Pfeiffer bacillus (*Haemophilus influ-*

*From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine and the Department of Bacteriology and Immunology, Harvard Medical School.

†Instructor in medicine and in bacteriology and immunology, Harvard Medical School; associate in medicine, Peter Bent Brigham Hospital.

enzae) is the commonest endemic form.² These organisms are frequently mistaken for meningococci by an inexperienced observer, because they may appear as gram-negative diplococci. They take stains with difficulty, and if *H. influenzae* infection is suspected, the smear should be stained with safranin for five or ten minutes, after which time the organisms will appear as quite small, very pleomorphic, gram-negative bacilli and cocci, often paired. Their early identification is essential, since specific rabbit-serum therapy offers the greatest hope in this highly fatal disease.^{3, 4}

Cultural Methods

Taking cultures. To obtain positive cultures from patients with infections, intelligent co-operation between the physician and his laboratory associates is needed. Swabs must be taken from the lesion itself, with as little contamination as possible. This is particularly true in throat cultures, when the results vary enormously with the technic of the person taking the cultures. It is hardly necessary to point out that swabs must be kept moist and planted as soon as possible, because most pathogenic organisms die more quickly than their saprophytic companions. Various technics have been devised for keeping the swabs moist and the organisms alive. If the material can be kept cold, dropping the swab in a tube of broth is a good policy. A few drops of physiologic saline solution or water in the bottom of the tube with the swab suspended a little above it may help. Never dip swabs in saline solution, since it is quite toxic for most organisms. An English worker devised an excellent scheme for meningococcus-carrier studies, which laboratories serving practitioners might well adopt. The bottom of the test tube is filled with a small amount of blood agar on which the swab is allowed to rest.⁵ As a general rule, all specimens do best if they are maintained at a temperature just above freezing during transport to the laboratory, rather than at warmer temperatures. This is particularly true of stool specimens, in which overgrowth of colon bacilli at room temperature will obscure the presence of a few pathogens.

Partial tension. A few tricks in the isolation of pathogenic organisms make a great difference. A slight increase in the carbon dioxide tension of the atmosphere stimulates the growth of bacteria. Furthermore, moisture has a marked effect, many organisms growing readily on fresh moist plates, and very poorly on old dry ones. The moisture can be conserved by covering the space between the Petri dish and its cover with Scotch tape or Parafilm, or by placing the Petri dishes in a museum or preserve jar, with moist blotting paper in the bottom and with a tightly fitting lid. Increased car-

bon dioxide tension can be secured in an individual plate culture by putting a small piece of carbon dioxide snow in the Petri dish cover, inverting the plate over it and sealing. For a group of plates in a jar, proper atmospheric conditions may be achieved by including several plates inoculated with *Bacillus subtilis*, as recommended by Fothergill and Sweet,⁶ or by lighting a candle in the jar and clamping the lid on tightly, as recommended by Nye and Lamb.⁷ I have found the latter method most convenient, because of its simplicity. The candle uses up a portion of the available oxygen, and produces water vapor and carbon dioxide; the last increases to about 3 per cent before smothering the flame, thus providing optimal conditions for the growth of such organisms as the meningococcus, gonococcus, *Streptococcus viridans*, hemolytic streptococcus, pneumococcus and staphylococcus. The first three organisms will frequently grow only under these mephitic conditions, whereas the others always grow more luxuriantly under them.

Anaerobiosis. Few laboratories have solved the problem of making satisfactory anaerobic cultures. It is extremely important, since many studies have shown that if routine anaerobic cultures could be done, a great many more isolations would be made. Even organisms like the hemolytic streptococcus and pneumococcus are occasionally obligatory anaerobes when first isolated. The inoculation of large (200 by 25 mm.) test tubes filled to at least half their depth with cooked-meat medium usually serves to support the growth of all anaerobic organisms, but isolation in pure culture from such tubes is difficult owing to the abundant growth of other bacteria. For single-colony isolation, no simple method has been devised, and one must use one of several cumbersome methods if anaerobic infection is suspected. The best method, which requires considerably less outlay than the original McIntosh-Fildes or Navy methods, is that devised by Weiss and Spaulding,⁸ and Spaulding and Goode,⁹ in which a jar is evacuated, filled with carbon dioxide, then re-evacuated and filled with hydrogen, which removes the remaining oxygen in the presence of palladinized asbestos as a catalyst. A chemical method that works fairly satisfactorily is that of Rosenthal,¹⁰ in which chromium is added to sulfuric acid, first liberating hydrogen, and later removing the oxygen by an oxidation of the chromous compound formed.* These methods make possible the inoculation of plates and the isolation of single colonies for identification. Brewer¹¹ has devised an extremely simple semisolid medium in which all anaerobes tested will grow and which is incubated aerobically. This

*This method has been greatly improved by Mueller and Miller.¹²

method is ideal for ascertaining the sterility of vaccines, toxic filtrates, and serums, but, of course, does not permit the isolation of organisms in pure culture. Its use as an anaerobic blood-culture medium has possibilities still to be explored. Cantor¹² has recently published an ingenious method with which he claims to be able to grow aerobes, mephitic organisms and anaerobes in the same plate incubated aerobically, and with this he can make single colony isolations.

Staphylococci. Staphylococci are so frequently isolated that it is difficult to assess their significance. The production of yellow pigment, although usually characteristic of virulent staphylococci, is not an adequate criterion of virulence, nor is hemolysis on blood-agar plates. The production of coagulase^{13, 14} seems to be quite closely correlated with human virulence, and can easily be tested. A staphylococcal colony or a loop of broth culture is emulsified in 0.5 cc. of citrated human plasma. If this clots within three hours at room temperature, the strain is strongly coagulase positive; if it clots after incubation overnight, it is weakly coagulase positive; and if it remains fluid, the strain is coagulase negative and probably not virulent. Julianella¹⁵ finds that the fermentation of mannite parallels the coagulase test, but it takes much longer. This test is very useful in determining whether a staphylococcus obtained in a blood culture is a probable invader or a probable contaminant, since most of the former are coagulase positive and the latter coagulase negative.

Streptococci. The proper identification of beta-hemolytic streptococci is extremely important, because infections with these organisms require treatment with sulfanilamide rather than sulfathiazole, and treatment should be continued for a long period to avoid relapses. Unfortunately, many laboratories are unaware of certain peculiarities of these organisms that make their identification difficult. A strain isolated from one of the severest infections seen at the Peter Bent Brigham Hospital was called *Streptococcus viridans* in the laboratory of another institution, because only surface inoculation of blood agar was used. The hemolysin that characterizes beta-hemolytic streptococci is inactivated by oxidation. Consequently, many strains do not produce clear zones of hemolysis on the surface of blood-agar plates, but do so only when pour plates are made and the colonies, growing deep in the agar, are protected from the direct effect of molecular oxygen. For this reason, pour plates containing 5 per cent horse, rabbit or sheep blood in infusion agar should always be made when hemolytic streptococci are suspected, that is, with throat swabs, mastoid swabs and

so forth. Dextrose-agar cannot be used, because the presence of dextrose often makes a true beta-hemolytic streptococcus produce green hemolysis. A further reason for making pour plates is that from their appearances beta-hemolytic streptococci of Groups A, B and C¹⁶ can be tentatively identified. Since Group B and Group C infections differ considerably in their course and response to sulfonamide drugs, this identification is of some practical value. If pour plates cannot be made, a simple expedient is to cut under the surface of the agar with the inoculating loop.

Another source of confusion is *Haemophilus haemolyticus*, or so-called "Bacillus X," which produces beta hemolysis both on the surface and in deep pour plates. The use of sheep's blood obviates this difficulty, since it inhibits the growth of this organism.¹⁷ If horse or rabbit blood is used, several hemolytic colonies must always be fished and smeared to make sure that no gram-negative filamentous bacilli are present and that the hemolytic organisms are gram-positive cocci. Mueller and Whitman¹⁸ found that dipping the swab in a dilute solution of disodium phosphate for an hour would get rid of *H. haemolyticus*.

Diphtheria bacilli. The isolation of the diphtheria bacillus from throat cultures has been greatly simplified by the introduction of tellurite-agar plates.¹⁹ On these plates the bacillus forms gray to black colonies. A tellurite-agar plate and Loeffler's slant should be inoculated with each swab. If the former shows suspicious colonies, a stained smear of the Loeffler's slant should be examined, since morphology of the organisms on tellurite agar is atypical. Inspection of the colonies will give an indication of whether the organisms are of the gravis, intermedius or mitis type, the mortality from the disease and the frequency of complications being closely correlated with the type of infection.²⁰

Meningococci. Cultures of spinal fluid in cases of meningitis should be made as rapidly as possible and on fresh chocolate-agar slants or plates, since this is the only medium that will grow all the organisms frequently causing meningitis (*H. influenzae* does not grow well on blood agar). At least one plate should be incubated in a candle jar, since increased carbon dioxide tension is necessary for growth of the meningococcus.

Gonococci. The culture of gonococci has been greatly improved and standardized in recent years, through the efforts of a number of workers. A few simple points deserve emphasis. The conditions for successful isolation seem to be the following: suitable mediums, fresh moist plates, slightly increased carbon dioxide tension and a

temperature evenly maintained at 36°C. The method of McLeod et al.,²¹ as adapted by Leahy and Carpenter,²² has become standard in many laboratories. This involves the use of chocolate-agar plates, incubation in a candle jar or similar container at 36°C. for forty-eight hours, and detection of colonies, when they cannot be identified by inspection and smear, by the oxydase reaction, using the dye para-amino-dimethyl-aniline-mono-hydrochloride. Other methods have been devised,^{23, 24} and one may expect further improvements in the coming years, since chemotherapy has emphasized the importance of cultural methods in ascertaining cures. It seems likely that the use of more than one type of medium may increase the percentage of positive cultures, since certain strains grow poorly on chocolate agar but luxuriantly on 20 per cent blood-dextrose agar. It must be emphasized that the gonococcus is an extremely delicate organism. In taking cultures, all anti-septic agents must be washed away from the genitalia after cleansing, and in females no lubricating jelly, other than plain sterile vaseline, should be used on the speculum, since such jellies contain antiseptics lethal to the organism.²⁵ Swabs must be planted as soon as possible, or kept in a small amount of ascitic fluid or broth, preferably in the cold until they can be planted. It is possible that the technic mentioned above of allowing the swab to rest on a small amount of blood agar in the bottom of a sterile tube during transportation may be satisfactory.

In differentiating gonococci and meningococci, agglutination tests, as well as agglutinin-absorption tests, are of little or no value because of the presence of cross agglutinins; sugar-fermentation tests in infusion broth containing ascitic fluid, which are controlled by tests set up with known strains, are usually employed.

Stool cultures. Cultures of the stool should be taken whenever possible in cases of acute and chronic diarrheal disease. Despite the marked fall in the incidence of typhoid fever, outbreaks of milder forms of enteric disease remain far too prevalent. These are caused mainly by members of the salmonella (paratyphoid) or dysentery groups. It should be stressed that, whereas in typhoid fever, stool cultures do not become positive until the later stages of the disease, in dysentery, stool cultures may be positive only during the first twenty-four to forty-eight hours. Since sulfaguanidine has been developed for the therapy of these infections,²⁶ accurate bacteriologic examination of fecal specimens becomes more important. Stool cultures should always be made within an hour or two after passage of the sample, or at least

the specimen should be kept cold until delivery to the laboratory. Otherwise, colon bacilli, which always outnumber the pathogens, will overgrow the latter to such an extent that the culture may be reported as negative.

Refinements in the technic involve the use of enrichment methods²⁷ and of newer mediums to supplant the time-honored eosin-methylene blue agar or Endo's agar plates. For general work, Leifson's²⁸ mediums—desoxycholate agar and desoxycholate citrate agar—seem to be the most satisfactory, since they permit heavy inoculation and a very clearcut differentiation between lactose-fermenting and nonlactose-fermenting strains.²⁹ For typhoid work only, Wilson and Blair's³⁰ bismuth sulfite agar is excellent, and could be used with advantage by all health-department laboratories in following the stools in cases of typhoid fever to see when the patients are ready for discharge.

Blood cultures. Blood cultures properly constitute a large part of the work of every diagnostic laboratory, since a positive blood culture is almost always significant. Contamination of blood cultures is relatively easy, and especial pains should therefore be taken to sterilize the skin thoroughly before venipuncture is performed, and to avoid any contamination with air-borne organisms. Most laboratories take blood cultures by direct inoculation of a flask of broth at the bedside. The citrate method is little more trouble to use and yields a great deal more information. Ten cubic centimeters of blood is removed and inoculated into a vial or flask containing 3 cc. of 2.5 per cent solution of sodium citrate, which prevents clotting. In the laboratory measured amounts (1 and 2 cc.) of blood are pipetted into two Petri dishes, and 10 cc. of dextrose infusion agar is poured into one and 10 cc. of plain infusion agar into the other. The remainder is pipetted into a flask of broth. The advantages of this method are: first, that it enables the laboratory to inoculate the type of medium best suited to the isolation of any particular organism; secondly, that it enables the bacteriologist to count the number of colonies per cubic centimeter of blood, giving a quantitative estimate of the degree of bacteremia; and thirdly, that more rapid identification of the organisms can be made from the type of hemolysis and appearance of the colonies when they grow out on the surface of the agar.

The choice of mediums for blood culture has always aroused considerable dispute.³¹ For routine purposes, dextrose infusion broth, dextrose infusion agar and plain infusion agar, the latter included for the identification of the beta-hemolytic

streptococcus, which produces alpha hemolysis in dextrose agar, will be found satisfactory. For isolation of the gonococcus, meningococcus and *Streptobacillus moniliformis*, the addition of 30 per cent ascitic fluid or animal serum is recommended. The isolation of *Brucella abortus* from the blood is often quite difficult,³² but 2 per cent tryptose broth and agar are recommended by Hudson et al.³³ Duplicate cultures should be set up aerobically and in a jar with 10 per cent carbon dioxide, which is necessary for the growth of *Brucella abortus*. In cases of suspected gas gangrene, puerperal sepsis or undiagnosed sepsis, at least one flask and plate should be incubated anaerobically, since anaerobic organisms invade the blood at times, particularly in these conditions. When gonococemia, meningococemia or subacute bacterial endocarditis is suspected, or when previous cultures have been negative in cases of suspected bacteremia, cultures should be incubated under partial tension with a candle jar or with *B. subtilis* cultures in the jar. All routine blood cultures should be held at least one week; cultures in suspected cases of subacute bacterial endocarditis, undulant fever, meningococemia or gonococemia should be kept three weeks before being discarded as negative.

Cultures from patients receiving sulfonamides
Since the introduction of sulfonamide therapy, the isolation of organisms from the body fluids of patients under treatment with these drugs has often been very difficult. Although such fluids frequently become sterile, cultures may be negative when viable organisms are present because of the marked in vitro bacteriostatic effect of the drug present in the inoculum. The discovery that *p*-aminobenzoic acid would inhibit the action of the sulfonamide drugs in vitro and in vivo^{34, 35} has made it possible to overcome this difficulty.³⁶ Para-aminobenzoic acid can be added to all routine culture mediums in a concentration of about 5 mg per 100 cc during their preparation and will withstand autoclaving at a pressure of 15 pounds for twenty minutes.³⁷ It has been found that if sputum from a patient with pneumonia who has been on chemotherapy is emulsified with an equal amount of a 0.1 per cent solution of *p*-aminobenzoic acid in saline and injected into a mouse, typable pneumococci may be obtained more rapidly and more regularly than when the sputum is injected alone.

IMMUNOLOGIC PROCEDURES

In addition to the direct evidence that the laboratory can supply by the isolation of the causative agent in infectious disease, indirect evidence of the nature of an infection may often be obtained by immunologic tests.

Skin Tests

Skin tests have been used for many years in medicine and are essentially of two types: those that depend on the direct toxic action of the injected material, and those that depend on a hypersensitiveness of the subject to the test substance.

The tests that depend on the toxicity of the test substance are the Schick and Dick tests for the detection of susceptibility to diphtheria and scarlet fever. A measured amount of toxin is injected into the skin. In a susceptible subject the toxin exerts its typical action—the production of an indurated, painful reddened lesion in three days with the Schick test, and of an area of erythema in twenty-four hours with the Dick test. If the subject has a level of circulating antitoxin arbitrarily considered sufficient to protect him from the disease, the injected toxin will be neutralized and no reaction will result. These tests may be misleading, particularly in adults, for in a person previously immunized by injection or contact with the offending organism, there may be little circulating antitoxin, but the cells may possess the ability to elaborate antitoxin very rapidly in response to a slight stimulus. Thus, two weeks after a positive Schick test, a repeat test may be negative, because the test injection has stimulated antitoxin production. Skin tests cannot be used to test for tetanus antitoxin, since tetanus toxin does not affect the skin. The reverse of the Dick test is made use of in the Schultz-Charlton test, in which scarlatinal antitoxin is injected into the skin of a patient with a red rash. If there is blanching at the site in twelve hours, the rash is considered to be scarlatinal.

Most skin tests depend on a state of hypersensitiveness induced by previous contacts with the test substance. This hypersensitiveness tends to assume one of two forms, which perhaps represent different degrees of the same thing, since in certain cases both forms appear at different times. Using Zinsser's³⁸ classification, one can divide hypersensitiveness into the anaphylactic type, in which circulating antibodies are present and therefore the hypersensitiveness can be transferred by injection of the serum into another person, and the allergic type, in which no humoral antibodies can be found, so that passive transfer is impossible. In the anaphylactic type, the injection of the test substance results in its union with and probable precipitation of the antibodies that exude into the site of injection. Such antigen-antibody complexes are extremely irritating and lead to the local liberation of a substance like histamine. Consequently the typical histamine reaction, a wheel with a zone of erythema about it, appears in about fifteen min-

utes and disappears within an hour or two. In the allergic type of reaction, nothing appears at the site for a number of hours, then induration, pain and redness occur, and in two or three days there is a hard, swollen, tender lesion, which resolves slowly and may even slough at its center. This appears to be due to an inherent sensitivity of the cells themselves, since tuberculin sensitivity has been demonstrated by the cells of a tuberculin-positive guinea pig after they have grown many generations in tissue culture.³³ In both types of reaction, the skin itself must possess the power to

injected antibody and to give a reaction. If normal rabbit serum is used, this reaction will not occur to confuse the issue.

Serologic Tests

Serologic tests are used in the diagnosis of disease on the assumption that the development of antibodies against a particular infectious agent or some of its products is evidence that the patient has suffered from an infection due to that particular agent. This assumption is based on two premises: that antibodies are specific, and that their

TABLE 1. *Clinically Important Skin Tests.*

CONDITION	TEST SUBSTANCE	REMARKS
IMMEDIATE (ANAPHYLACTIC) REACTIONS		
Asthma, hay fever, food allergy, serum sensitivity and so forth	Extracts of pollens, foods, serum and so forth	Some patients skin sensitive without symptoms
Helminth infections (trichiniasis, ^{40 41} echinococcal disease)	Extract of worms	In trichiniasis delayed reaction first, later replaced (14-20 days) by immediate reaction
Pneumococcal pneumonia (Francis test ^{42 43})	1:10,000 dilution of capsular polysaccharide of infecting type	Patient must be tested before treatment is begun. If test positive then, cannot be used. If negative, first appearance of positive test after serum administration indicates development of excess of antibody.
DELAYED (ALLERGIC) REACTIONS		
Tuberculosis*	Old tuberculin, P.P.D. (purified protein derivative) better ⁴⁴	
Brucellosis*	Brucellergen, ^{45 46} brucella vaccine	
Tularemia*	Detoxified <i>Past. tularensis</i> vaccine (Foshay ⁴⁶)	
Lymphopathia-venerea (lymphogranuloma-inguinale) (Frei test)	Inactivated bubo pus, ⁴⁷ inactivated infected mouse brain, ⁴⁸ inactivated infected chick-embryo extract ⁴⁹	The last test material is recommended as most satisfactory; all but the first are commercially available.
Chancroid (dmeleus test)	Vaccine (Duerey's bacillus)	Seldom needed for diagnosis
Pseudoreactions (Dick and Schick tests)	Schick and Dick controls (culture filtrate heated to inactivate toxin)	Due to hypersensitivity to bacterial protein in culture filtrate

*The test remains positive for many years after infection, whether clinical or subclinical. Therefore, its value in diagnosis is in inverse ratio to the frequency of exposure to the infection. Negative tests are valuable in excluding infection.

react to the irritation, and in moribund patients this often disappears.

A summary of skin tests that are of greatest value in the diagnosis and treatment of disease is given in Table 1.

Foshay⁴⁶ has described a sort of reverse Francis test for the early diagnosis of tularemia. Instead of injecting antigen to detect antibodies, he injects antibody to detect antigen. Since the antigen is apt to be circulating early in a disease like tularemia, the injection of specific antiserum is apt to give an immediate reaction. Such tests are seldom necessary and must be carefully controlled with normal serum of the same species. However, Foshay's work is important in emphasizing that skin tests for serum sensitivity must be done with normal serum. Thus, for example, in Type 1 pneumonia, if the rabbit serum to be used in treatment is diluted and injected intradermally, the test is frequently positive, because enough capsular polysaccharide usually circulates to unite with the

formation is always induced by a specific stimulus. These premises have a solid immunologic foundation, because specificity is the most striking characteristic of serologic reactions. But one must be exceedingly cautious in defining specificity. Antibodies have a specific affinity for certain chemical groupings or spatial arrangements, as the work of Landsteiner⁵⁰ and many others has shown, but there is nothing to prevent these groupings from occurring in a number of bacteria and viruses. It is this sharing of chemical groupings by dissimilar organisms that gives rise to bizarre phenomena, such as the Weil-Felix reaction, in which the serum of a patient with typhus agglutinates a certain strain of *Proteus*. As Castaneda⁵¹ has shown, this agglutination is due to the presence of a certain carbohydrate in both the typhus rickettsia and this strain of *Proteus*. Furthermore, in patients who possess antibody against one antigen, the stimulation of antibody production by another infection may produce a rise in the titer of anti-

body against the first antigen as well; this is known as the *anamnestic* reaction.

Since antibodies develop in response to an infection, samples of blood should be drawn early in an infection to serve as a control against later ones. If a single sample of convalescent serum shows antibodies, it means little, but if a sample taken near the onset shows no antibodies, the positive test later means a great deal. To interpret a single serologic test it is necessary to know the frequency of positive tests in the section of the population to which the patient belongs, the titers that can be considered within normal limits and the past history of the patient.

All serologic reactions depend on a union of the antibody in the serum with the antigen for which it has a specific chemical affinity. This union is the fundamental reaction, but it cannot be detected unless secondary reactions take place, which depend on the physical state of the antigen and the conditions of the test.⁵² If the antigen is in solution (for example, horse serum) and antibody is added in a test tube, a precipitate will form, if electrolytes are present. If the antigen and antibody unite in the body, anaphylactic reactions occur that give rise to an immediate type of reaction in the skin and to anaphylactic shock in the internal organs. If the antigen is particulate (bacteria or colloidion particles coated with a soluble antigen⁵³), agglutination will occur when antibody is added in the presence of electrolytes. In the presence of leukocytes, phagocytosis will take place. If complement is present when union of antigen and antibody occurs, it will be fixed by the antigen-antibody complex, and its fixation can be tested by the addition of sensitized sheep cells; such tests must be used when the bacteria will not form satisfactory agglutinating suspensions, as with the gonococcus, or when the antigen cannot be obtained in pure solution, as with virus infections.

The reaction of antigen and antibody has certain peculiarities due to the colloidal nature of antibodies, which account for the zone effects, seen particularly in high-titer serums. Thus, when a patient's serum agglutinates typhoid bacilli to a dilution of 1:2560, there may be very little agglutination below a dilution of 1:80 or 1:160. This is a very strong argument for the use of the test-tube agglutination method with graded dilutions instead of slide agglutination, in addition to the fact that it gives much better quantitative results. Furthermore, the colloidal nature of these reactions requires that they be carried on under relatively constant conditions with regard to pH and concentration of antigen, if results are to be reproducible. Thus, the bacterial suspension used for agglutination reactions must be standardized

in some way, the simplest being comparison with turbidity standards of barium sulfate.⁵⁴ Test tubes must be thoroughly rinsed after cleaning, since alkalinity from residual soap or acidity from residual cleaning solution will markedly affect the sensitivity of the test. The isoelectric point of most bacteria is in the neighborhood of pH 4.0, and at this point they will flocculate spontaneously, whereas the isoelectric point of the antibodies with which they unite is about 5.6, and at this point agglutination would theoretically be most marked, but not necessarily specific.

Below is given a list of the serologic tests that are of proved value in the diagnosis of disease, with some comments.

PRECIPITATION TESTS

Syphilis (Hinton, Kahn, Kline, Kolmer and Eagle tests). These are very useful, since their ease of performance and high sensitivity make them ideal for the exclusion of syphilis. A comparison of the various tests has been made.^{55, 56}

Parasitic Infections. In trichiniasis and echinococcal disease, patients usually develop high titers of precipitins, as well as positive skin tests.^{40, 41}

Pneumonia. Test for the presence of capsular polysaccharide in the blood and urine may be a valuable guide to prognosis and thus to therapy.⁵⁷

Spinal Fluid. A ring at the interface between spinal fluid and influenzal or meningococcal antiserum indicates meningitis with the corresponding organism.²

AGGLUTINATION TESTS

Brucellosis. Agglutinins when present in titer of 1:80 or more are usually significant. The test is often negative in chronic infections or may be positive in normal subjects in endemic areas, particularly after acute infections.⁵⁸

Tularemia. Agglutinins nearly always rise, usually to high titers, and persist for many years.

Pneumonia. Agglutinins are considered by many to be the most satisfactory method for titrating antibodies.⁵⁹

Dysentery. Agglutinin titer seldom rises high. Occasionally an agglutination test is useful, when positive stool cultures are not obtained. Tests with the Sonne and Shiga types are quite specific; the Flexner group is antigenically heterogeneous.

Salmonella Infections. In this group of infections, agglutination tests are of great value. The work of Kauffmann and White⁶⁰ has revealed an extraordinary number of antigens in the group. A properly performed Widal test should include the various organisms that cause enteric fever in the local area. For New England this would be *Eberthella typhosa*, *S. schottmulleri* (paratyphoid B), *S. suispestifer*, *S. enteritidis* and *S. aertrycke*. Two types of agglutination occur: the so-called "H" or flagellar agglutination due to sensitization of the flagellar antigens, and the "O" or somatic agglutination caused by sensitization of the bacterial bodies. H agglutination

is rapid (two hours at 55°C.), and large floccules are formed. O agglutination requires six to twelve hours at 55°C., and fine granular masses are formed. To detect O agglutinins either a nonmotile strain or a specially prepared suspension treated with heat to destroy the H antigen must be used. O agglutinations are very important in doubtful cases, because although a high H agglutinin titer may be produced by prophylactic vaccination or the anamnestic reaction, O agglutinins seldom appear above a titer of 1:80 except in response to infection, when they usually parallel H agglutinins.⁶¹

Infectious Mononucleosis (heterophil agglutinin test).

Serums in this disease agglutinate sheep and ox red blood cells in high titers. This may be associated with a false positive serologic test for syphilis.⁶²⁻⁶⁴

Rickettsial Infections (Weil-Felix reaction). Patients recovering from rickettsial infections agglutinate certain *Proteus* strains. Typhus group agglutinates OX₂ and OX₁₉, tsutsugamushi group OX-K, spotted fever group both strains.⁶⁵

COMPLEMENT-FIXATION TESTS

Syphilis (Wassermann test).

Gonococcal Infections. The gonococcal complement-fixation test is much abused. Antibodies appear only infrequently in response to local genitourinary infections, but do appear in a high percentage of cases of endocarditis and arthritis. The test is useless in following the course of local gonorrhea, but very useful in the differential diagnosis of arthritis and bacterial endocarditis.

Serologic Diagnosis of Diseases Due to Filterable Viruses

Since filterable viruses cannot be grown on ordinary culture mediums and are often isolated with the greatest difficulty by experienced investigators, the diagnosis of these diseases is impossible for the ordinary laboratory. Isolation of the virus is seldom feasible, but the diagnosis of some of these infections by serologic tests is a practicable procedure in well-equipped laboratories, such as those of the Rockefeller Institute, the National Institute of Health or the bacteriology departments of the large medical schools. In virus diseases it is very important to collect serum in the acute stage of the disease and then at the optimum time for the appearance of antibodies, usually three or four weeks after the onset. In many virus diseases, soluble antigens, chemically and immunologically distinct from the virus itself,^{66, 67} have been found, and antibodies to these antigens appear in the serums of convalescents usually somewhat earlier than protective antibodies against the virus. These antibodies can be detected by complement fixation, and have been used in the diagnosis of influenza,⁶⁸ lymphocytic choriomeningitis,⁶⁷ psittacosis⁶⁹ and lymphogranuloma ingui-

nale.⁷⁰ Antibodies to the virus itself must be detected by their ability to prevent the development of disease in response to a known strain of virus in laboratory animals. Such neutralization or protection tests are widely used in investigative work.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27191

PRESENTATION OF CASE

A sixty-one-year-old Jewish merchant entered the hospital complaining of increasing dyspnea and fatigue.

Two years before admission, the patient noticed the onset of increasing fatigue and shortness of breath, and complained of a feeling of pressure over his left chest. Dyspnea gradually increased in severity and appeared with even the slightest exertion or when he was lying on his back or his left side. Only on his right side could he lie comfortably. On two occasions eight months before admission, while lying in bed, the patient brought up a mouthful of bright-red blood without clots. He did not vomit at the time, nor was he coughing. For several months before entry, while hurrying upstairs, he had experienced a sensation of tightness in his neck, accompanied by a dull ache in the region of the antecubital space of the left arm. These symptoms disappeared immediately with rest. In general the patient had felt well, although he was easily fatigued; his appetite was good and there had been no weight loss.

The patient had had scarlet fever at nine years. His mother, father and one brother had died of heart disease.

On examination the patient was well developed and well nourished and in no apparent distress. The chest was barrel-shaped, with flaring of the costal margins and a suggestion of Harrison's groove. The trachea was shifted to the right, as were the borders of cardiac dullness. There were dullness to percussion and diminished breath sounds and tactile and vocal fremitus over the entire left upper-lung field anteriorly, these same signs being present posteriorly on the left down to the level of the second thoracic spine. The heart sounds were distant, but otherwise normal. One examiner found a blood pressure of 180 systolic, 100 diastolic, in the right arm and 155 systolic, 95 diastolic, in the left; this difference was not recorded by others. The abdomen was normal. Examination of the nervous system was negative except for asymmetry of the face, which was believed to be the result of an old Bell's palsy on the left.

The temperature, pulse and respirations were normal.

Examination of the urine was negative, and kidney-function tests were normal. The blood showed a red-cell count of 4,900,000 with a hemoglobin of 15.1 gm. (photoelectric-cell technic), and a white-cell count of 8500. The nonprotein nitrogen of the blood serum was 24 mg, the protein 6.5 gm. per 100 cc.; a blood Hinton reaction was negative. No tubercle bacilli were found in the sputum on three occasions.

An electrocardiogram showed normal rhythm at 70, with a PR interval of 0.2 second; T₁ was inverted, T₄ was very low and triphasic, and there was slight sagging of ST₂.

An x-ray examination of the chest showed a huge oval mass occupying the anterior aspect of the left side of the chest and extending between the anterior ends of the second and sixth ribs. The mass showed calcification at its margin, moved upward with the ribs at inspiration and displaced the heart to the right. The aorta and heart were otherwise normal, and the diaphragm and visible portions of the lungs were also normal. There was no definite evidence of disease in the ribs, although the anterior ends of the third and fourth ribs were indistinct.

An operation was performed three weeks after admission.

DIFFERENTIAL DIAGNOSIS

DR. FREDERICK T. LORD: May we see the x-ray films?

DR. JAMES R. LINGLEY: The films show this very large mass on the left side of the chest. In the lateral view it lies anteriorly, being flattened against the anterior chest wall. In this film with a little more exposure, one can see a thin rim of calcification around the superior margin. The mass is very smooth and sharply defined, and seems to be slightly lobulated in some areas. The aorta appears normal. The heart is displaced to the right but is not appreciably enlarged. The x-ray appearance is more in favor of tumor than of aneurysm, and the presence of calcification in the wall suggests a benign tumor, especially a cyst.

DR. LORD: The shortness of breath on exertion and on lying on the back or the left side, and the sense of pressure over the left side of the chest, suggest encroachment on the thoracic space, with resulting cardiac disturbance.

The tightness in the neck and the dull ache in the left antecubital space may be ascribed to a disturbance in the circulation in the heart muscle, arising either in consequence of encroachment by the mass or as a result of intrinsic disease of the muscle.

The hemoptysis eight months before admission may have been due to congestion from venous pressure or to erosion of the air passages.

The presence or absence of cough is uncertain, and it is desirable to include a definite statement with respect to this symptom. Although the sputum was examined for tubercle bacilli, its character is not described. A statement regarding the presence or absence of wheezing is also lacking.

That the patient was easily fatigued is interesting, but difficult to interpret. That the appetite was unimpaired and the weight maintained is probably significant.

The flaring of the costal margins and the suggestion of Harrison's groove imply that a tug on the diaphragmatic attachments over a long period led to a bending deformity, and that the intrathoracic mass may have been present for a much longer time than the history indicates.

The complex of physical signs is consistent with the presence of a circumscribed collection of fluid or a solid mass without communication with the bronchi. Failure to mention rales leaves us uncertain about their presence or absence.

The trachea and the heart were displaced somewhat to the right. The blood pressure was slightly elevated. There is a question of difference in the level of the blood pressure in the right and the left arm. The facial asymmetry is not to be regarded as Horner's syndrome.

There are no significant blood findings, with the exception of the negative Hinton reaction, which makes aortic aneurysm unlikely.

The abnormal features of the electrocardiogram may be ascribed to one of three possibilities. They might be due to the administration of digitalis (and we should like to know if the patient had had digitalis), to the slight dextrocardia or to myocardial disturbance. Unless digitalis was administered, I am inclined to think that the electrocardiographic findings are secondary to the encroachment on the intrathoracic space by the mass, but I hope we may have the comments of the cardiologists on this matter.

Since a substernal goiter is a possibility, a basal metabolic rate would be of interest, but is probably of no great importance in the absence of other indications of an overactive thyroid gland. An echinococcus fixation test is desirable in such a problem.

With respect to the source of the mass, without cough or wheezing, an origin in the bronchi or lung is improbable, and the absence of pleural fluid seems to exclude the pleura unless it is an encapsulated pleural process. The mediastinum seems the most likely point of origin, and the lo-

cation in the left chest was apparently due to least resistance to enlargement in that direction.

With respect to the nature of the mass, an aneurysm is unlikely because of its apparent lack of connection with the aorta in the x-ray films, in addition to the negative Hinton reaction already mentioned.

Various types of tumor are to be considered. A malignant tumor is unlikely, although an originally nonmalignant process may have become malignant. We are therefore left with nonmalignant tumors. The evidence does not warrant a definite diagnosis, and the best I can do is to enumerate the possibilities. Some reliance may be placed on the relative frequency of different types of tumor as a guide in the chance relation, but I appreciate that the chance relation can be upset by Dr. Mallory's assignments.

Neurofibroma is to be considered, but the site of this tumor in the anterior aspect of the thorax makes it unlikely. Lipoma, thymoma, intrathoracic goiter and echinococcus cyst are possibilities. But of all the possibilities, on the basis of the evidence here and the chance relation, I should lean rather more heavily toward a dermoid cyst. If it is a dermoid cyst, it was present at an unusually advanced age. In Hedblom's* series of 191 cases, only one occurred in a patient between sixty-one and seventy years of age. It is to be remembered, too, that about 10 per cent of these cysts become malignant. A positive diagnosis can be made only by finding such elements as hair, squamous epithelium and sebaceous material.

DR. EDWARD D. CHURCHILL: The problem that was uppermost in our minds in dealing with this patient was the question of advisability of operation. The patient was sixty-one years of age; his mother, father and one brother had died of heart disease. He had changes in the electrocardiogram that were interpreted as not due to the tumor, or displacement of the heart. These changes indicated that the patient might be expected during the course of the coming years to develop clinical manifestations of coronary heart disease. Is that putting it fairly, Dr. Bland?

DR. EDWARD F. BLAND: No digitalis had been given?

DR. CHURCHILL: No.

DR. BLAND: I should say so.

DR. CHURCHILL: This prognosis seemed important relative to operation, because this patient could be expected to continue to complain of precordial pressure in the chest referred down his arm and accompanied by increasing dyspnea. In other

*Hedblom, C. A. Intrathoracic dermoid cysts and teratomata with a report of six personal cases and one hundred and eighty five cases collected from the literature. *J. Thoracic Surg.* 32:2, 47, 1933.

words, we were faced for an indeterminable period with a differential diagnosis between intrinsic coronary disease and symptoms due to this tumor. Again, it seemed to me that in a patient who might be expected to develop myocardial insufficiency any factor that could be a burden on the heart, either mechanically or indirectly through limiting vital capacity, should be removed. The patient would then be in a better situation to face his oncoming coronary disease.

We considered, as Dr. Lord did, that this tumor was benign. However, one possibility that we wanted to exclude definitely was putting this elderly patient through an operation for a tumor that might be malignant and had better be treated by x-ray than surgery. For this reason, needle aspiration biopsy was performed. It was really done as part of the operation. A needle was inserted, and a cloudy, brown fluid withdrawn, which under the microscope showed fat and fatty-acid crystals. This finding, of course, gave a definite preoperative diagnosis of dermoid cyst. If I had encountered a solid tumor, I should have tried to secure enough tissue for microscopic diagnosis, and I should have reconsidered the question of radiation therapy if the tumor proved to be malignant sarcoma or teratoma. After having confirmed the diagnosis, however, we went ahead with the operation.

DR. LORD: I should like to ask Dr. Bland if he thinks he could ascribe the electrocardiographic changes to dextrocardia.

DR. BLAND: No; I am sure you cannot.

DR. TRACY B. MALLORY: Dr. Churchill, do you want to tell us your operative findings?

DR. CHURCHILL: It was a dermoid cyst. We took it out, and the patient recovered.

DR. BLAND: Do you think it might be of interest to repeat the electrocardiogram, just on the chance that the T waves might have been altered?

DR. CHURCHILL: Yes; we shall do so.

CLINICAL DIAGNOSIS

Benign tumor of mediastinum (dermoid cyst ?).

DR. LORD'S DIAGNOSIS

Nonmalignant tumor (dermoid cyst ?).

ANATOMICAL DIAGNOSIS

Dermoid cyst of mediastinum.

PATHOLOGICAL DISCUSSION

DR. MALLORY: Dr. Robert Klopstock studied this cyst with the aid of x-ray films after it had been opened. Most of the calcified material was not an integral part of the wall but merely an

adherent precipitate that could be fairly easily scraped off. A few amorphous masses were embedded in the wall, but there was no organization, and no formation of bony trabeculae as in a teratoma.

DR. CHURCHILL: Dr. Taiana is here from the Argentine. I should like to ask him if that would pass for an echinococcus cyst in the Argentine, where that disease is so prevalent.

DR. JORGE A. TAIANA: If this lesion with calcification were an echinococcus cyst, it would have to be a dead echinococcus cyst. In cases like this we do not find round masses. Usually we find a cavity, more or less clean, with fluid and with hydatid membrane broken into it. The picture here is completely different.

DR. GEORGE W. HOLMES: How much fat was there in the tumor?

DR. MALLORY: Just masses of crystalline fatty acids and cholesterol suspended in the fluid.

A PHYSICIAN: Was the patient completely relieved?

DR. CHURCHILL: He said he was, both physically and mentally.

CASE 27192

PRESENTATION OF CASE

A forty-five-year-old man entered the hospital complaining of exertional dyspnea, cough and weakness.

For the last ten years, the patient had had a morning cough productive of mucoid sputum. Approximately two years before entry, he noticed the onset of shortness of breath on exertion, with a heavy feeling in the chest. His cough grew worse and produced larger quantities of mucoid material, but at no time had it been malodorous or had it contained pus or blood. He consulted his physician, and an x-ray examination of the chest showed bilateral bullous emphysema, with the changes more pronounced on the right, the largest bleb measuring 12 cm. in diameter. He carried on until two months before admission, when the initial symptoms became exaggerated and generalized weakness appeared. An x-ray examination at this time showed the same emphysematous changes, with low diaphragms, but in addition an irregular soft-tissue density in the right paratracheal region, which measured 9 by 8 by 7.5 cm., displaced chiefly the upper lobe and deviated the trachea to the left. Another film nine weeks later demonstrated no change in these findings. The patient stated that during these few weeks before admission he had been given six x-ray treatments, and that coincident with this therapy he had started to vomit, usually in the morning after breakfast and sometimes following

a spasm of coughing. Gradually his generalized weakness increased, and one week before admission a sudden weakness appeared in both legs, which was so severe that he was unable to lift them out of bed. At the time of entry, strength had partially returned in the left leg. During the two months' illness, the patient had suffered from frontal headaches and had lost considerable weight. At twenty he had had gonorrhea, and eight years before admission a right nephrectomy for renal stone. His mother had died from cancer of the uterus.

On examination the patient was pale, weak and cachectic; there was cyanosis and clubbing of the fingers, with an appreciable elevation in the venous pressure. The chest was emphysematous, with slightly less expansion on the right; it was hyperresonant throughout. Scattered rales were heard throughout the chest, most noticeably at the right base. The heart sounds were distant, the blood pressure 108 systolic, 70 diastolic. Abdominal examination was negative except for a right nephrectomy scar. The cranial nerves were normal, but the extremities were wasted and the reflexes on the right side of the body were more active than those on the left. There were ankle clonus and a positive Hoffmann sign on the right; the Babinski signs were normal. Slight but definite motor weakness was present in the right leg and arm (the patient was left-handed), and he performed the heel-to-knee test poorly with his right leg.

The temperature was 101°F., the pulse 100, and the respirations 25.

The urine was normal. The blood showed a red-cell count of 5,080,000 with a hemoglobin of 94 per cent, and a white-cell count of 15,200 with 76 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 30 mg. per 100 cc.; a blood Hinton reaction was negative. A lumbar puncture was normal, with a negative spinal-fluid Wassermann reaction. The sputum was negative for tubercle bacilli on one occasion; the stools were normal.

An x-ray film of the chest showed a lobulated mass in the upper anterior mediastinum in close relation to the aorta, but without definite pulsation. No calcification was seen within the mass, and the aorta proximal and distal to it appeared normal. The heart was normal in size and shape. The lungs showed extensive, extremely large, emphysematous bullae, and there was a round 15-cm. shadow in the right anterior lower-lung field. Laminaeograms showed the mass in the upper mediastinum to be almost exclusively on the right side. It was markedly lobulated, and a separate mass was visible posteriorly in the right tracheobronchial angle. A gastrointestinal series showed displac-

ment of the esophagus to the right and posteriorly by the mass in the upper mediastinum. Otherwise there was no evidence of disease in the upper gastrointestinal tract.

The cough increased. Three weeks after admission, the patient began to suffer from transient episodes of acute dyspnea, which lasted but a few minutes and were associated with clonic contractions of the right leg and twitching of the muscles, with jerking of the entire extremity. Gradually the cough became almost constant, and the sputum thick, tenacious and mucopurulent; and one month after admission the right side of the body was completely paralyzed. Finally, a chest plate showed consolidation in the lower portion of the right lung field consistent with pneumonia, and the sputum yielded a Type 20 pneumococcus. The tumor mass had not changed appreciably so far as could be determined. Death occurred six weeks after admission.

DIFFERENTIAL DIAGNOSIS

DR. LOWREY F. DAVENPORT: We have three separate and somewhat unrelated problems here. The patient had extensive pulmonary emphysema, he had a tumor in his chest, and he apparently died of an intercurrent infection due to the pneumococcus. I think we might take up these three points separately and later see if there is any relation among them.

The background and etiology of pulmonary emphysema are obscure in most cases. Obviously, at the time he came into the hospital, the patient had right-sided heart failure, which is curious because in certain types of extensive emphysema there is no evidence of right-sided heart failure. The emphasis seems to lie in the association of certain emphysematous changes in the lungs to secondary sclerosis in the pulmonary artery. When this pulmonary condition does not occur we get very little change in the mechanics of the right side of the heart. If this were primary pulmonary sclerosis with secondary emphysema, the story would have been entirely different, with a long-standing history of cyanosis, the picture of a "black cardiac," or Ayerza's syndrome, which we often speak of and rarely see. I believe we can exclude a primary pulmonary sclerosis as a cause of the emphysema. At the age of forty-five, it certainly is not senile emphysema. We see considerable emphysema associated with long-standing asthma. That is not the case here. It is interesting that the patient had a cough for ten years. At the time he came in he also had clubbed fingers. If we exclude any primary difficulty with the right side of the heart and with the pulmonary circulation, we have to assume that the clubbed fingers were due to the changes going

on in the lung itself. I do not believe that the cardiac history as given here is sufficient to account for the clubbing of the fingers, nor does emphysema itself cause it. With a ten-year cough, assuming that the patient gradually developed emphysema and later developed right-sided heart failure, it seems to me we have to predicate a long-standing infection. If we try to tie up the extensive emphysema with infection, we can do so only by assuming extensive bronchiectasis involving finer bronchioles, so-called "bronchiolar bronchiectasis." The ordinary suppurative type, with a tremendous amount of infection, very quickly gives clubbed fingers, but is not associated with generalized emphysema. The mass in the chest was discovered almost incidentally. In going through the history, I could find no correlating data with which I could tie up the mass in the chest with the emphysema and the right-sided heart involvement.

May we see the x-ray films at this point?

DR. JAMES R. LINGLEY: The films show an extreme degree of emphysema as described, with large blebs and bullae throughout both lungs, the largest being in the apices, where the appearance simulates a pneumothorax. In addition there is this mass projecting to the right from the upper mediastinum. In the lateral view it extends anteriorly. The laminagraph brings out the margins of the mass a little better. It is sharply defined and lobulated, and the aortic arch appears to be pushed a little to the left side and may be a little dilated in the region of the arch.

DR. DAVENPORT: How intimate was its relation to the aorta?

DR. LINGLEY: Certainly it was in contact with the aorta.

DR. DAVENPORT: We have here an unquestionable tumor in the chest, with very meager definitive data to arrive at the diagnosis. There are several things that may be helpful in trying to untangle the nature of this mass. I think, in general, we believe that a lobulated mass in that region is usually lymphoma, and the obvious signs, which I should interpret as cerebral manifestations, also fit in very well with this diagnosis. However, the lack of response to x-ray therapy is decidedly against it. If it was not lymphoma, what other type of tumor could it have been? I think we must assume that in a man of forty-five the coincidental cerebral symptoms prove it to have been a malignant tumor. On statistical grounds, the diagnosis lies, then, between a cancer and a lymphoma. The shape of the mass is rather against cancer. Bronchiogenic carcinoma should give signs of obstruction. Cancer close to the hilus of the lung, usually does, and only those situated in the periphery, chiefly the adenocarci-

nomas, would grow to this size without giving clinical and x-ray signs of atelectasis.

The blood findings are somewhat against a cancer that had reached the stage of metastasis. This man came in with a red-cell count of 5,800,000. In our experience, about half the patients with cancer of the lung show a secondary anemia by the time they present themselves for diagnosis. We have to be careful of one thing in this case: the patient may have had a moderate amount of polycythemia on the basis of pulmonary changes and right-sided heart changes, so that for him a hemoglobin of 94 per cent and a red-cell count of 5,000,000 might have represented a drop. Unfortunately, we have no data to support that. In spite of the fact that this tumor did not respond to six lymphoma doses of x-ray therapy, I consider lymphoma the most likely possibility.

There is little to say about the terminal course. The patient had bouts of dyspnea, which do not fit in very well with right-sided heart failure and the changes going on in the lung parenchyma. Perhaps they were cerebral in origin. I think it is also true, if he had metastasis to the brain, that any anoxia of the brain might precipitate convulsions. As a matter of fact, in epilepsy we make use of overbreathing experiments and various types of provoked dyspnea to bring out irritability in the brain.

Having drawn this picture of a man who slowly developed emphysema on the basis of changes in the bronchi and repeated infection, who had what I shall call a malignant lymphoma in the chest and who died of terminal pneumonia and evidence of brain metastases, are there any loopholes in this diagnosis? Is there anything we should go back and try to tie up? He had a nephrectomy eight years prior to admission for renal stone. It does not seem likely that he could have had a hypernephroma at that time that could have been missed.

DR. TRACY B. MALLORY: Are there any suggestions?

DR. EDWARD F. BLAND: I should like to raise some objection to the emphasis placed on right-sided heart failure on the evidence given in this record. It seems to me that the only thing that makes one suspect that the heart might have been involved is that the patient had pulmonary disease of some sort for a long time. The second point is the swelling of the veins in the neck. There are conditions other than right heart failure that give full veins in the neck, for example, mediastinal obstruction. It might have been helpful if something had been said about pulsations in the veins in the neck, because usually there is an absence of pulsations if the swollen veins are the result of mediastinal obstruction in contrast to pul-

sating swollen veins due to back pressure from right-sided heart failure. It is a little unusual to get serious failure of the right side of the heart without some enlargement or dilatation of the heart detectable by physical examination or by x-ray study, and in the films the heart certainly does not look enlarged to me.

DR. GEORGE W. HOLMES: I was going to point out the same thing that Dr. Bland has: that the heart is small and there is no evidence of right-sided enlargement.

DR. BLAND: Another point is that the liver was not felt, and I think we must assume that it was not enlarged. No mention is made of edema, and I doubt therefore if right-sided heart failure was an important feature of the illness, even though at postmortem the right ventricle may be found thicker than normal (cor pulmonale).

May I ask Dr. Davenport or Dr. Churchill about this question of pulsating veins in the neck? Is that a reliable differential point between back pressure due to mechanical obstruction as opposed to heart failure?

DR. EDWARD D. CHURCHILL: I should have expected a rise in venous pressure with emphysema from the reduced negative intrathoracic pressure.

DR. RALPH ADAMS: It seems to me that that lateral view shows atelectasis of a part of the upper lobe, and I should suggest that it is a primary bronchiogenic carcinoma arising in the upper lobe. If that suggestion should prove to be correct, one might explain the signs in the neck by secondary pressure on the vena cava.

DR. CHURCHILL: How common are intracranial metastases of lymphoma?

DR. MALLORY: They are not at all common, but are not extremely rare.

DR. CHURCHILL: As a focal lesion?

DR. MALLORY: Viets and Hunter* a few years ago reported five cases of cerebral lymphoma with focal lesions. In leukemia it is commoner to have infiltration without focal signs.

DR. CHURCHILL: The patient had a little nodule in the lung opposite the one affected. The so-called "primary tumor," in addition to the brain manifestations, speaks very strongly for cancer, it seems to me.

DR. HOLMES: Why do you drop aneurysm without any comment? I am not saying that I think it is an aneurysm, but I wonder how you rule it out so easily.

DR. DAVENPORT: I think we are forced to rely on you. I assumed, when Dr. Lingley said that the mass was attached to the aorta but was not a part of it, that aneurysm could be excluded. I should not be willing to accept that information from a film not combined with fluoroscopy.

DR. LINGLEY: The mass is rather lobulated, too.

DR. ADAMS: Is it uncommon in the experience of the X-ray Department to see a mass that size in one part of the mediastinum and so little in all the rest?

DR. HOLMES: I should say so.

CLINICAL DIAGNOSIS

Carcinoma of lung, primary and metastatic.

DR. DAVENPORT'S DIAGNOSES

Malignant lymphoma of mediastinum and brain.

Pulmonary emphysema.

Right-sided heart failure.

ANATOMICAL DIAGNOSES

Bronchiogenic carcinoma, with mediastinal and cerebral metastases.

Pulmonary emphysema.

Bronchopneumonia.

Cor pulmonale.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The post-mortem examination showed very extensive emphysema, with large bullae running up to 5 and 10 cm. in diameter. There was a tumor that filled the upper anterior mediastinum and surrounded the great vessels, causing, I am sure, significant venous stasis by mechanical pressure in the thoracic inlet. There was also a tumor in the central portion of the right upper lobe, the appearance of which was characteristic of a primary bronchiogenic carcinoma. It had invaded the pulmonary artery to that lobe, which was nearly occluded by a combination of tumor and secondary thrombus. So far as the rest of the lung was concerned, Dr. Davenport correctly prophesied an extensive terminal bronchopneumonia. There was no marked pulmonary fibrosis, and the appearances were those of idiopathic emphysema, with nothing to give one any lead as to its cause. We did not particularly note bronchiectasis, but I am not prepared to say that it was not there. A bronchiectasis of the smaller radicals is sometimes hard to differentiate from emphysema, and the picture was further obscured by the pneumonic consolidation. The smaller branches of the pulmonary artery showed no sclerotic changes. The right ventricle measured 7 mm., which is quite definite evidence of cor pulmonale, since the heart as a whole was not hypertrophied. A single metastasis, about 2 cm. in diameter, was found in the upper portion of the motor cortex on the left. No metastases were found elsewhere in the body. Microscopically the tumor was a highly undifferentiated carcinoma, probably squamous cell in type.

DOCTORS FOR BRITAIN

THE American Red Cross has issued an appeal for 1000 American physicians to serve with the British Red Cross in caring for military and civilian war casualties. Volunteers accepted by the British Red Cross will serve either as medical officers with the Royal Army Medical Corps or as physicians with the Emergency Medical Service, a civilian organization under the direction of the Ministry of Health. In addition to the endorsement of the leading professional groups in this country, this appeal has the approval of the Secretary of War, the Surgeon General of the Public Health Service and the President of the United States.

The task of treating civilian casualties, of providing medical care in the large factories and in

the expanded navy, army and air corps, and of dealing with the manifold problems incident to wholesale bombing of cities, particularly in preventing epidemics, has proved insurmountable for the medical profession in England. The call for volunteers merits the quick and eager response of American physicians.

The need is urgent, the dangers many, and the rewards almost unlimited. Service with the British Red Cross offers a rare professional experience in the medical technics of modern warfare. Even more important, however, is the opportunity of helping not only soldiers in combat but also those on the other firing line of defense: the population of the ruined cities of the British Isles.

THE FRANCIS AMORY PRIZE

NEARLY thirty years ago there died in Beverly an elderly gentleman, Mr. Francis Amory, after a long illness complicated by the miseries of prostaticism. His will bequeathed in trust to the American Academy of Arts and Sciences the sum of \$25,000, to be allowed to accumulate for twenty-one years, after which the income was to be devoted to a prize to be awarded once in every seven years for the purpose of encouraging and rewarding those engaged in studying, perfecting and publishing methods for the relief of diseases that he described as, "diseases and derangements of the human sexual generative organs in general, and more especially for the cure, prevention or relief of the retention of urine, cystitis, prostatitis and so forth." The testator also suggested that the award may be made to the discoverer of "any notably useful remedy," or to the inventor of "any cunning device or instrument," or if such a person fails to appear, to the writer of "any exceptionally meritorious treatise" on these subjects.

The Academy accepted the trust, and for the first time the income has become available for distribution in the current year. As is so often the case in such bequests, the terms imposed by the testator have been quite difficult to carry out in such a way as to observe their conditions, to do justice to all possible candidates for the prize,

and to promote the public interest. The provision that the work to be recognized must have been done during the seven-year period just preceding the award, and the question whether it is permissible to consider important scientific research the connection of which with the advances described by the testator as the object of his generosity is somewhat remote and indirect, have been the chief perplexities. A committee of the Academy, under the chairmanship of Dr. Roger I. Lee, after long inquiry and deliberation, and with the aid of legal advice when necessary for interpretation of the will, has divided the award among four candidates: Dr. Hugh Young, professor of urology, Johns Hopkins University School of Medicine; Dr. Joseph F. McCarthy, director, Department of Urology, New York Polyclinic Medical School and Hospital; Dr. Carl R. Moore, professor of zoology, University of Chicago; and a European scientist whose name is withheld at present, because he is a citizen of one of the victim states of the Reich, and there is reason to believe that the award would be confiscated or harm be done him by his amiable *Gauleiter*. The accomplishments of Dr. Young, Dr. McCarthy and Dr. Moore that justify the honor to be conferred on them are known to all students of the functions and diseases of the urogenital organs.

The award is to be made at a meeting of the American Academy of Arts and Sciences to be held on the evening of Wednesday, May 14, at 8:15 at 28 Newbury Street, Boston. All interested physicians are invited to attend.

MEDICAL EPONYM

BUNDLE OF HIS

The original description of this structure, by Wilhelm His, Jr. (b. 1863), is found in the article "Die Thätigkeit des embryonalen Herzens und deren Bedeutung für die Lehre von der Herzbeugung beim Erwachsenen [The Activity of the Embryonal Heart and Its Significance in the Theory of the Contraction of the Adult Heart]," which appeared in *Arbeiten aus der medizinische Klinik zu Leipzig* (14-49, 1893). A portion of the translation follows:

After prolonged investigation, I have succeeded in finding a muscular bundle that connects the auricular and the ventricular septums. This has hitherto escaped observation because, on account of its small dimensions, it is visible in its entire extent only if this area is cut lengthwise. Up to the present time, I have been able to trace the course of the bundle in such sections and also in serial sections in a grown mouse, a newborn dog, two newborn infants and one adult (thirty years) human being. The bundle arises from the posterior wall of the right auricle near the auricular septum in the atrioventricular groove, continues along the upper margin of the ventricular septum with frequent interlacing of the muscle fibers of the two structures, and then runs forward until, near the aorta, it forks, dividing into a right and left branch. . . .

MASSACHUSETTS MEDICAL SOCIETY

ANNUAL MEETING OF THE COUNCIL

The annual meeting of the Council will be held in the Swiss Room of The Copley-Plaza, Boston, on Wednesday, May 21, 1941, at 10:30 o'clock.

Business:

1. Presentation of record of special meeting held April 9, 1941, as published in the *New England Journal of Medicine* for May 8, 1941.
2. Nominating Committee retires to deliberate.
3. Reports of standing and special committees.
4. Election of officers and orator.
5. Appointment of committees for ensuing year, both standing and special.
6. Incidental business.

DEATH ASSOCIATED WITH INFECTION AND STILLBIRTH

A thirty-five-year-old multipara arrived at the hospital in active labor at term with a temperature of 103.6°F. She had never been examined during this pregnancy, and had had no prenatal

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

care whatsoever. The past history was essentially noncontributory. The patient had three living children, but more specific information concerning the labor and delivery in these pregnancies was not obtained. There was no history of previous medical complications.

Physical examination on entrance was essentially negative. There was no evidence of anything abnormal in the lungs; no mention was made of the throat. The heart was rapid, with a rate of 120, but there was no mention of a complicating disease. The uterus was enlarged to a size consistent with full-term pregnancy, the membranes had ruptured, apparently shortly before admission, and the patient was in active labor. After ten hours and forty minutes, the patient was delivered normally of a stillborn child. Death occurred twenty hours after delivery.

Comment. This is a most unusual story. There was nothing in the history to explain the infection that must have been present, and unfortunately, permission for an autopsy was not obtained. In the absence of evidence of pneumonia, — which, if present, would undoubtedly have been recognized, — it seems likely that the patient was suffering from a generalized infection, possibly streptococcal in origin. Obviously, cultures of the blood and lochia should have been made.

The stillbirth was probably due to the fever, but early intrauterine sepsis is a possibility. Since this maternal death occurred in 1937, before the advent of chemotherapy, one cannot judge what the outcome would have been if the patient had been treated with one of the sulfonamides.

APPLICANT FOR FELLOWSHIP

Owing to an error, the following name was omitted from the list of applicants for fellowship printed in the April 10 issue of the *Journal*.

PLYMOUTH DISTRICT

Bernard H. Beuthner, 24 School Street, Middleboro.
University of Breslau, 1925.

Ralph C. McLeod, *Secretary*.

DEATHS

HOLT—**CHARLES H. HOLT, M.D.**, of Pawtucket, Rhode Island, died April 26. He was in his sixty-first year.

Born in Bradford, England, Dr. Holt attended Brown University and received his degree from the Harvard Medical School in 1906. He was president of the Rhode Island Medical Society, and was a fellow of the American Medical Association and a former member of the Massachusetts Medical Society.

His widow, two sisters and a son survive him.

WELLES—**DELBERT A. WELLES, M.D.**, of Fitchburg, died May 1. He was in his seventy-eighth year.

Born in Concord, New Hampshire, he attended Thetford Academy, Vermont, and received his degree from George Washington University School of Medicine in 1898. He trained in government hospitals for six years before going to Fitchburg. He had been a city councillor since 1939.

He was a fellow of the Massachusetts Medical Society and the American Medical Association.

MISCELLANY

NOTES

On May 5, Dr. Walter B. Cannon, George Higginson Professor of Physiology, Harvard Medical School, was presented the Friedenwald Medal of the National Gastroenterological Association. This was the first award of the medal, and the accompanying citation read, "In recognition of his pioneer utilization of the x-rays in gastroenterology, and his important contributions to the mechanics of digestion, to the elucidation of the sensations of hunger and thirst, and to the development of the science and practice of gastroenterology."

The two awards of \$100 each offered by the Laymen's League Against Epilepsy in 1940 for the best original unpublished observations or investigations bearing on the subject of epilepsy have been granted as follows: for work done in a state epileptic colony or mental hospital, to Dr. Walter L. Bruetsch, Central State Hospital, Indianapolis, Indiana, "Rheumatic Epilepsy"; for work done elsewhere, to Dr. Frederick A. Fender, Stanford University Hospital, San Francisco, "Convulsions Following Remote Electrical Stimulation of Subcortical Cerebral Levels."

At a meeting of the Trustees of Middlesex University, held on April 12, the following new trustees were appointed: Stanley R. Latshaw, Haddam, Connecticut; Alton L. Miller, Brookline; Joseph F. O'Connell, Boston; Charles J. O'Malley, Boston; and Samuel H. Wragg, Needham Heights, Massachusetts.

CORRESPONDENCE

"TEN-DAY PAPER" FOR ADMISSION TO STATE MENTAL HOSPITALS

To the Editor: It seems advisable to call to the attention of the medical profession the basic provision and intent of Section 79, Chapter 123, General Laws, which is the authorizing statute for a temporary-care, so-called "ten-day paper," admission of a patient to a mental hospital within this commonwealth.

This statute provides in part that the superintendent of a hospital for the insane may, upon request of certain designated persons, receive as a patient for a period not exceeding ten days a person who is "in need of immediate care and treatment because of mental derangement other than drunkenness."

There appears to be a general impression that this type of admission is primarily a *ten-day observation*. Scrutiny of the statute does not support this view. It is intended to provide an *emergency admission* for the patient who must be hospitalized immediately, and who should not await usual commitment proceedings before admission for reasons of his own personal welfare or the safety of the public.

Other sections of Chapter 123 provide for observation in a mental hospital. Section 77 authorizes the usual thirty-day observation, Section 100 includes observation for those under complaint or indictment, Sections 103 and 104 allow observation for those under sentence for crime.

It is therefore recommended that the use of the ten day paper be restricted to those cases in which the patient is in need of immediate care and treatment because of mental derangement other than drunkenness.

MEDICAL OFFICER WANTED FOR THE SCHOOLSHIP NANTUCKET

To the Editor The Massachusetts Nautical School is desirous of securing the services of a medical officer for the Schoolship *Nantucket* for the summer cruise of 1941 the itinerary of which covers 8245 miles, ending in Boston on September 9.

The medical officer of the *Nantucket* will have charge of safeguarding the health of 85 cadets, and of the officers and crew, numbering about 30. It is important to have a man not only of good professional ability but of the highest character.

W K QUEEN, *Commander*

Boston

REPORTS OF MEETINGS

BOSTON ORTHOPEDIC CLUB

There was a regular meeting of the Boston Orthopedic Club at the Boston Medical Library on January 20 with Dr Augustus Thorndike, Jr, presiding.

The first paper was by Dr A B Ferguson and was entitled 'Wedging Round Back of Adolescence'. This condition has been described under various titles, including vertebral epiphysitis and Schuermann's disease. It is characterized by gradual development of anterior wedging of one or more of the dorsal vertebral bodies during adolescence and is a common condition. The patient with a wedging round back has poor posture, with round shoulders and exaggeration of the posterior curve of the dorsal spine, the anterior cervical and lumbar curves are increased, and the abdomen may be protuberant. Fatigue is the commonest symptom before and during adolescence, but later rigidity of the spine may reduce fatigue. Pain is not common in those who are quite young but is frequent at and after the age of seven years, when osteoarthritic changes may be evident.

In a group of these cases studied for possible etiologic factors it was found that the condition was not confined to a particular type of person, that debilitating disease may favor its development, that the frequency of such conditions as coxa plana and Osgood-Schlatter's disease was not sufficient to suggest an etiologic relation, and that familial tendencies may favor its development, although obviously, the condition is not wholly congenital. Dorsal round back may be noted clinically, but the diagnosis of wedging round back of adolescence is usually a roentgenographic problem because it is necessary to rule out by roentgen examination certain other causes of round back or kyphosis, such as fracture hemivertebra, incomplete segmentation, malacia, chondrodysplasia,

rheumatoid arthritis and specific infectious diseases. The features of this condition are progressive multiple anterior rounded wedging of the dorsal vertebral bodies. The wedging may progress indefinitely, but there is rarely much increase after the age of twenty. During adolescence irregularity of the intervertebral disks and apophyseal plates may be evident, and at or after the age of seventeen osteoarthritic calcareous lipping may be present. The vertebral bodies do not become ankylosed, nor do they present areas of destruction or abscess formation.

Since immobilization in plaster has failed to prevent the progress of the deformity and the presence of pain, weakness and fatigue, it was considered likely that inflammation, which should be benefited by such a regimen, is not the etiologic factor in wedging round back of adolescence. From a consideration of the development of the vertebral column and a review of the progress of cases in which x-ray films taken before adolescence were available, Dr Ferguson concluded that in certain persons a persistence of a vascular area at the middle of the vertebrae anteriorly weakens the structure and results in compression where the stress is greatest—in the dorsal region. It was emphasized that the wedging occurs by compression at the middle of the anterior surface of the body, not by compression of the upper or lower surfaces. The apophyseal plates appear later roentgenographically and the irregularity found in this condition was considered a secondary phenomenon resulting like the later osteoarthritic lipping, from impaired nutrition. In this conception, there is no need to assume the presence of disease in the vertebral body or elsewhere. It is simply that all people do not have spines entirely suited to the erect posture.

The treatment indicated for the prevention of deformity, fatigue and pain should be reduction of stress on the front portion of the vertebral bodies in the dorsal area. This treatment can be very simply accomplished by means of a postural brace, a modification of an ordinary short spinal brace. The usual horizontal bars at the buttocks and vertical bars along the spine are retained, but at the upper extremity of the vertical bars a padded metal block is placed. The height of the brace is such that the pad impinges on the back immediately below the area of the round back deformity. The brace does not itself support the dorsal spine, but maintains a lumbar posture that excites active extension of the dorsal spine. The brace is not effective for older patients, when the spine is not flexible, the adolescent period of rapid growth having been passed.

Treatment of wedging round back of adolescence at the New York Orthopedic Hospital has been mainly along conservative lines. Nearly all the patients had exercises to strengthen muscles and keep the spine mobile. In a few cases, a short spine brace, such as that described above, was used and in others the spine was fused surgically in the deformed area, with or without an attempt to correct the deformity. Treatment by exercises did not prevent increase of deformity or the development of ache or fatigue. The results of surgical fusions were not, on the whole, an improvement over the results obtained by exercises. Fusion of the area of greatest deformity did not prevent progress or maintain correction of the deformity except in a few cases, nor was there a demonstrable favorable effect on the tendency to increasing pain and fatigue with advancing age. Nevertheless some patients with distressing fatigue and pain were much better after spine fusion, and such treatment may be of

sential in such cases. As a rule, if deformity did not increase in the fused area, it did increase in the areas adjacent to the fusion, and it seems that one could not expect to prevent increase of deformity in the adolescent unless the entire dorsal spine were fused; however, there seems to be no justification for extensive surgery in the treatment of such a mild condition. Use of the brace definitely tended to inhibit the progress of deformity and the development of symptoms in adolescent and preadolescent patients. When ache or fatigue is marked the patient is apt to be too old to derive benefit from the brace. If the spine has become too stiff to straighten definitely when the brace is applied, it is too late to derive benefit from the brace. Wedging round back of adolescence should be diagnosed in the preadolescent years, when the simple treatment by postural brace may prevent the development of troublesome deformity.

During the discussion, Dr. John J. Kuhns suggested that the roentgenographic appearance of a persistent vascular canal may be an artefact. In 1000 autopsies at the Children's Hospital, with many clinical diagnoses of wedging round back, no pathologic changes were found. Furthermore, not all adults with a persistent canal have evidence of past or present wedging round back. Treatment should be carried out early, but Dr. Kuhns finds that many patients need elaborate jackets rather than simple back braces, which probably are effective only where there is a well-developed postural reflex.

Dr. Joseph Barr, of the Massachusetts General Hospital, agreed that there was an interference of epiphyseal growth rather than an epiphysitis. He believes that the presence of tight lower extremities may cause an increased lumbar lordosis and a functional kyphosis. As for treatment, it is found that exercises help materially even when roentgenographic evidence does not confirm the improvement.

In answer, Dr. Ferguson replied that the x-ray evidence undoubtedly is not artefact. He suggested that those patients with roentgenographic evidence but no clinical disease have minimal vascular impairment or good musculature and posture, whereas persistence of the vascular canal in the lumbar region causes no symptoms because of the absence of stress. In regard to the hip flexion mentioned by Dr. Barr, it was stated that this is usually present in the older patients, and therefore is more probably a secondary phenomenon.

The second paper, "A Recently Defined Destructive Lesion of Bone," was presented from the clinical aspect by Dr. William T. Green and from the pathological by Dr. Sidney Farber. The authors reported the occurrence of destructive lesions in the bones of 10 children, all under twelve years of age, studied at the Children's Hospital during the last ten years. The disease process was limited almost completely to the destructive lesions in the skeletal system. These lesions were either single or multiple and involved mainly the flat bones, particularly the skull, ribs and pelvis. They were seen in many other bones, but never at the distal ends of extremities. When single, the lesions had the roentgenographic characteristics of solitary bone cysts. The multiple lesions could be compared most accurately in distribution and punched-out appearance with either myeloma or metastatic cancer. More than twenty-six areas of involvement of the skeleton were noted in one patient. The presenting sign was usually swelling or pain. Swelling was more prominent than pain when the skull was involved. Healing occurred readily under roentgen-ray therapy. Nine of the 10 patients were apparently well when examined recently. One patient died outside the hospital; the details cannot be obtained.

Biopsy specimens were obtained from all the lesions. The microscopic picture varied considerably, but in general it was essentially a granulomatous process in which eosinophilic infiltration was frequently a prominent feature. Activity of the marrow cells in the involved areas was evident in several cases to such an extent that a picture characteristic of myelocytic myeloma was suggested by the initial studies. Various gradations from the purely granulomatous reaction to a definite xanthomatous process could be demonstrated in various sections examined. Small to large amounts of lipids, stainable by the Scharlach R method, were present in the lesion.

The lesion clinically and microscopically conforms to a picture recently described under the name "solitary granuloma of bone" or "eosinophilic granuloma of bone." A comparison of the pathologic material obtained from these 10 patients with the bone and visceral lesions found in Schüller-Christian's disease and with pathologic specimens from the lungs, lymph nodes and skin of a condition that has come to be known in recent years as Letterer-Siwe's disease has led to the conclusion that all three conditions represent variations of the same basic disease process. Preliminary bacteriologic and animal-inoculation studies have thus far been negative in the group under discussion, as well as in Schüller-Christian's disease and Letterer-Siwe's variation of that disease. Further studies of the etiologic basis for the benign destructive lesion under discussion, as well as of the other variants of the Schüller-Christian syndrome, are under way. There appears to be no justification, on the basis of this experience, for considering eosinophilic or solitary granuloma of bone as either a new or a separate disease entity.

HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on January 28, with Dr. Elliott C. Cutler presiding.

The first case was that of a sixty-nine-year-old man who entered the hospital because of intense jaundice and itching. For four months he had noticed weight loss and increasing lassitude and fatigue. Three weeks before admission he had been troubled with constipation and crampy right lower-quadrant pain. Anorexia had been present for two weeks, jaundice for five days and nausea for one day. There was no previous history of right upper-quadrant pain or other gall-bladder complaints. Physical examination revealed a chronically ill, emaciated, jaundiced man in no distress. The abdomen was tender in the right upper quadrant; the liver edge could be palpated 2 cm. below the right costal margin, and was round, firm and nontender. Laboratory data revealed normal red-cell and white-cell counts, a +++ test for bile in the urine, an icteric index that rose from 50 to over 100, a blood diastase positive at 1:68 and normal plasma-protein levels and liver function tests. Roentgenograms demonstrated an extrinsic mass deforming the duodenum. The probable diagnosis of pancreatic neoplasm was made, but Dr. Merrill C. Sosman stated that such a diagnosis could not be made from x-ray studies alone, for tumors cannot be seen until they are very large, and may well be cysts instead of neoplasm.

The second case was that of a sixty-nine-year-old man who entered the hospital because of anorexia of one month's duration. His stools had become increasingly lighter and his urine darker, and two weeks before admission his friends had noticed that he was jaundiced. He had had some vague chest pains, which radiated to

right side, and there had been an indefinite weight loss. Physical examination revealed a well developed, emaciated and jaundiced elderly man. There was an apical stolic murmur without any cardiac enlargement. The abdomen was large, and without any tenderness or masses. The liver descended 3 cm below the costal margin, and its edge was smooth and firm. There was a rect inguinal hernia on the left side. The icteric index was 60, and the bleeding and clotting time normal. A ray study was negative. The patient was operated on, and cholecystogastrostomy carried out, with subsequent decrease of symptoms of jaundice, improvement in the color of the stools and urine, and a drop in the icteric index to 30. Dr Sosman stated that here again no preoperative diagnosis was possible, but that postoperatively roentgenograms there was no increase of the gall bladder induration and no regurgitation of barium into the gall bladder. Dr Cutler pointed out that the usual type of anastomosis may allow infection to ascend into the liver, and this has led to the valvular type of anastomosis employed by Dr Zollinger. In this patient, the patient had been anesthetized to allow full and painless respiration immediately after operation.

The paper of the evening was 'Carcinoma of the pancreas' delivered by Dr Frank Glenn, of Cornell University Medical College. As an introduction the speaker pointed out that this disease annually causes most as many deaths as pulmonary cancer. Pathologically, cancer usually appears in the head (70 per cent). Association with biliary disease is not constant, and nodules may be diffuse or scattered. Metastases to regional lymph nodes are found in 90 per cent of cases. In the liver in over 50 per cent, there are peritoneal implants in less than half the cases, and skeletal spread is present in 20 or 30 per cent. Microscopically there may be a cylindrical adenocarcinoma from the duct system that tends to be cystic, a tumor with large granular cells similar to those of the alveoli, or an islet-cell carcinoma. The incidence of the condition was found to be 1 in 12 hospital admissions. The chief complaint was pain in 68 per cent of patients, jaundice in 50 per cent and occasionally other symptoms. The high incidence of pain was emphasized, and it was noted that there is apt to be more itching from this type of jaundice than from that of a common-duct stone. The leading symptom as loss of weight (97 per cent). On physical examination jaundice was found in 68, hepatomegaly in 53 abdominal tenderness in 37 and a palpable gall bladder in only 34 per cent of the cases. In regard to laboratory findings, blood counts were found to be variable, stools were found to contain blood in over half the cases, but no other data were considered significant. The importance of guaiac positive stools as evidence of intestinal invasion was suggested. Roentgenograms were carried out in the majority of cases and were reported negative in 50 per cent. Of the remaining half, defects were noted in the pylorus and all portions of the duodenum, with diagnosis of probable carcinoma of the stomach, duodenal ulcer and carcinoma of the head of the pancreas in equal numbers. The duration of life after the onset of signs and symptoms was found to average only slightly over nine months.

Treatment was variable and discouraging. Palliative operations apparently relieved the biliary obstruction decreased the itching and increased the appetite. The occurrence of cholangitis was discouragingly frequent, the mortality was high, and the duration of life was not increased. Curative operations, which attempt to extirpate the tumor, have been found technically difficult and

there is the added disadvantage that the patients do poorly postoperatively, probably owing to the inadequacy of attempted substitutes for the external pancreatic secretions. Dr Glenn considers the external secretions important for maintaining proper pancreatic and hepatic functions, for ligations of the ducts in dogs lead to fibrosis and decrease of active pancreatic tissue and an early and marked increase in the liver fat. He proposes to preserve the secretions by transplanting the duct containing pancreas to the posterior stomach wall. In animals, the pancreas has been found grossly and microscopically normal while the patency of the ducts is maintained and the liver remains normal. Dr Glenn therefore advocated removal of the tumor bearing area and transplantation of the remaining ducts to the posterior stomach wall. Of 3 possible cases operated on, 2 of the patients have shown too much induration around the head of the pancreas at the second stage, whereas the third was found to have cancer at the ampulla of Vater. It was therefore suggested that one-stage operations might be advisable. One important feature of this type of operation is the impossibility of any ascending infection.

In conclusion Dr Glenn suggested that the hope for the future lies in earlier diagnosis and in improved and more radical surgery. The important clues for earlier diagnosis are abdominal pain, loss of weight and jaundice without any other definite cause. Improvement in treatment should include earlier and more frequent exploratory operations.

The discussion was opened by Dr David Cheever, who pointed out that the pancreas should be considered in both the acute (pancreatitis) and the chronic (carcinoma of the head of the pancreas) surgical abdomen. He has found in the latter condition that although pain is common, it is not similar to that of biliary colic. Instead, it is usually vague and persistent, and radiates toward the back or left flank. Roentgenographic studies are of questionable value, even when the tumor is in the head, and entirely miss those in other parts of the gland. Cases have usually seemed inoperable, owing to seeding of the peritoneum, especially in the right upper quadrant. Dr Cheever believes that cholecystogastrostomy offers the most favorable prognosis at present, for it usually affords a year and a half of fairly comfortable existence, often followed by sudden death.

Dr S. J. Thannhauser stated that diagnosis can be facilitated by the use of the double-barrel duodenal tube and the secretin test. He is of the opinion that the findings of 80 to 90 milliequivalents of alkali per liter following secretin is significant. He has found that pain below the left costal margin may simulate that of cardiac origin. He stated that in his opinion choline is not related to the fatty metabolism of the liver in man. He has had no good results with the feeding of raw pancreas.

Dr J. E. Dunphy has also found the incidence of pain to be about 68 per cent, but he differentiates the site of the lesion by the character and site of the pain. Obstruction of the ducts by a small tumor is apt to produce colicky pain, which diminishes as the disease progresses; in other cases, there is an ache in the back, with vague abdominal pain, which is worse at night and when the patient is recumbent, large tumors of the body of the pancreas may affect the celiac plexus and cause excruciating pain, which may radiate even to the chest.

Dr Sosman stressed the importance of diagnosis by exclusion, for loss of weight in 97 per cent of cases indicates that failure to lose weight can fairly well rule out

this condition. The possibility of relieving pain by irradiation in inoperable cases was advanced.

The meeting was closed by Dr. Glenn, who suggested that not only the alkalinity but also the volume following the use of secretin is significant. He has found irradiation therapy inefficacious in allaying pain. He has observed glycosuria intermittently in 14 per cent of his preoperative patients, whereas Opie has found evidence of true diabetes in 10 per cent of such cases at autopsy.

NOTICES

FRANCIS AMORY AWARDS

Members of the medical profession are invited to attend a meeting at the American Academy of Arts and Sciences, 28 Newbury Street, Boston, on May 14, at 8:15 p.m., for the occasion of the presentation of the Francis Amory Awards to three investigators for their notable contributions to the treatment and cure of diseases and derangements of the genitourinary organs.

The investigators are Dr. Joseph F. McCarthy, professor of urology and director of the Department of Urology, New York Polyclinic Medical School and Hospital; Dr. Carl R. Moore, professor of zoology, University of Chicago; and Dr. Hugh H. Young, professor of urology, Johns Hopkins University School of Medicine.

Each recipient will briefly describe his investigations, placing special emphasis on the circumstances leading to the culmination of the work for which the prize is given.

TRUDEAU SOCIETY OF BOSTON

The annual meeting of the Trudeau Society of Boston will be held at the Belmont Hospital, Worcester, Massachusetts, on Thursday, May 15, at 4 p.m.

PROGRAM

Pulmonary Tuberculosis and Pregnancy. Dr. Arthur D. Ward.

Discussion by Drs. Samuel C. Gwynne, Francis D. Hart and Frederick L. Good.

Carcinoma of Lung and Tuberculosis. Dr. Marguerite D. Shepard.

Discussion by Drs. Ernest L. Hunt and Ralph H. Adams.

Rectal Fistula in the Tuberculous. Dr. Percy A. Brooke.

Discussion by Dr. Andrew Taylor, of Hartford, Connecticut.

Treatment of Guinea Pig Tuberculosis with a New Chemical Compound. Drs. Raymond H. Goodale and Leslie A. MacClintock.

Gomenol Therapy in Pulmonary Tuberculosis: Presentation of cases. Dr. Robert H. Baker.

Discussion by Drs. Donald King and Nahum R. Pillsbury.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston,

on Tuesday, May 20, at 12 m. Dr. Henry Jackson, Jr., will speak on "Certain Practical Aspects of Blood Disorders as Seen by the General Practitioner."

Physicians are cordially invited to attend.

BOSTON DISPENSARY

There will be a clinical staff meeting of the Boston Dispensary in the Pratt Hospital Auditorium on Friday, May 16, at 12:30 p.m. Dr. Burrill B. Crohn, chief, Gastrointestinal Service, and associate in medicine, Mt. Sinai Hospital, New York City, will speak on "Sprue versus Ileojejunitis." Luncheon will be served at 12 m.

All interested members of the profession are cordially invited to attend.

1941 GRADUATE FORTNIGHT

The 1941 Graduate Fortnight of the New York Academy of Medicine will be held from October 13 to 24. The purpose of this meeting is to make a complete study and authoritative presentation of a subject of outstanding importance in the practice of medicine and surgery. The current topic is "Cardiovascular Diseases, including Hypertension."

There will be a carefully integrated program that will include morning panel discussions, afternoon clinics and clinical demonstrations at hospitals of New York City, evening addresses and a scientific exhibit. The evening sessions at the Academy will be addressed by recognized authorities from leading medical centers of the United States and Canada. The comprehensive exhibit will include books and roentgenograms, pathological and research material, and demonstrations of clinical, laboratory and therapeutic methods.

The following subjects will be included: basic hemodynamic principles essential to the interpretation of cardiovascular disorders; heart failure; diagnosis and treatment of coronary insufficiency; pathology of arteriosclerosis, with special reference to coronary arteries; observations on social significance and recent advances in the treatment of arteriosclerosis; advances in the knowledge of endocarditis, with special reference to the therapy of subacute bacterial endocarditis; neurocirculatory asthenia and related problems in military medicine; syphilis of the cardiovascular system; arrhythmias, including paroxysmal tachycardia and their treatment; the value and limitations of the electrocardiogram in medical practice; evaluation of drugs used in the treatment of cardiovascular diseases; surgery of the heart and large vessels; surgical treatment of peripheral embolism and peripheral aneurysm; thrombophlebitis; the use of heparin; Raynaud's disease; thromboangiitis obliterans; experimental studies related to shock; influence of extrinsic factors on the coronary flow and the clinical course of heart disease; treatment of heart disease in childhood; management of heart disease in pregnancy; mechanism of essential hypertension; mechanism and treatment of pulmonary edema; rheumatic heart disease; and effects of renal excretory products of hypertension.

The Academy provides this program for the fundamental purpose of postgraduate medical education; consequently all members of the medical profession are eligible for registration. A complete program and registration blank may be secured by addressing: Dr. Mahlon Ashford, New York Academy of Medicine, 2 East 103d Street, New York City.

anisms in plants and animals, biological basis of social
problems, regeneration* Edited by Jaques Cattell, with a
foreword by George A Baitsell, PhD 8", cloth, 270 pp,
with 13 illustrations and 1 table Lancaster, Pennsylvania
The Jaques Cattell Press, 1941 \$2 50

BOOK REVIEWS

The Management of Obstetric Difficulties. By Paul Titus, M.D. Second edition. 8°, cloth, 968 pp., with 368 illustrations and 5 color plates. St. Louis: The C. V. Mosby Company, 1940. \$10.00.

The title *The Management of Obstetric Difficulties* is hardly broad enough to include all the valuable material presented in this volume. For instance, the first two chapters are devoted to the treatment of sterility, including a well-illustrated discussion of the treatment of absolute sterility in the male.

The section on the complications of pregnancy contains many valuable features, including a detailed discussion of the so-called "minor complications" and the treatment of various systemic diseases and conditions requiring surgery during pregnancy. The important subject of infections of the urinary tract is well covered.

The methods of diagnosis and treatment in cases of ante-partum hemorrhage are by no means standardized, and naturally not everyone will agree with the author's opinions. He does not mention the latest advances in soft-tissue roentgenography in the diagnosis of placenta previa; he favors cesarean section in cases of complete separation of the placenta, in spite of recent statistics that show a lower mortality following normal delivery.

Two chapters deal with the toxemias of early and late pregnancy, and this subject is particularly well covered by the author, who has devoted much study to it.

Complications of labor, obstetric operations and complications of the puerperium are considered in detail. The author is conservative with regard to the use of pituitary extract in the first stage of labor, to the point of withholding it, even in small doses, in patients who are suffering from uterine inertia. Emphasis is properly placed on strict asepsis in connection with all obstetric surgical procedures, and all the operations are described in minute detail.

Two chapters are devoted to the care of the newborn infant, and the last four chapters deal with the actual preparation for delivery and aftercare of the patient, including a discussion of the various types of obstetric anesthesia and analgesia, and concluding with a description of the technic of preparation and injection of dextrose solution and of blood transfusion. Here, again, the subjects, although interesting and useful, do not seem to belong in a book devoted to obstetric difficulties.

Because of its attention to detail, this book is particularly useful when an unusual complication is encountered; it is to be recommended for ready reference.

A Review of the Psychoneuroses at Stockbridge. By Gaylord P. Coon, M.D., and Alice F. Raymond, A.B. 8°, cloth, 299 pp., with 66 tables and 2 figures. Stockbridge, Massachusetts: Austen Riggs Foundation, Incorporated, 1940. \$2.00.

From the standpoint of psychotherapeutics, this is an excellent book. It gives in detail and very cogently the technic used at Stockbridge and the results obtained. Whatever statistical evaluation is made of the results, however, is to a certain extent impaired by the fact that the patients are a highly selected group: first, financially, and secondly, by reason of their background of training and experience. In other words, the segment of psychoneurotics under consideration is probably far more accessible to the treatment described in this book than any other conceivable group of sufferers from neuroses.

One might easily criticize the classification of the types discussed in the first part of the book. When the seven groups are viewed objectively, it is found that practically every conceivable type of personality develops neurosis, since the classification goes all the way from the group of "overly ambitious, conscientious, dynamic, energetic persons" in Group A to the "immature, dreamy, romantic persons" of Group E, and includes all the way-stations of personality in between. To attribute a neurosis to hard, driving work without enjoyment and then to find that people of opposite temperament develop exactly the same symptoms cancels the classification of causes or of pertinent factors that are probably nonrelevant.

The reviewer still believes that the cause of the neurosis is unknown. One can postulate, in the present state of knowledge, that emotional stress, maladjustment in life, trouble or trauma—physical or mental—precipitates symptoms. But the essential basis is still a matter for future research to uncover. Adding inconclusive factor to inconclusive factor, no matter how many times, does not bring conclusiveness. Nor does the comparison of results of the Stockbridge cases with those of other institutes seem very convincing. The Stockbridge sample includes only neurasthenia or anxiety states, whereas that of the New York Psychiatric Institute, for example, includes compulsion neuroses as well, probably patients extremely unfortunate in all the circumstances of life, and also those having severer neuroses, that is, those leading to commitment or at least care in a hospital for mental disease. This at once excludes the minor cases.

Despite these criticisms, the book is, on the whole, excellent. It is clear, frank and intelligent in its discussion of the neuroses. The concluding section, which deals with mental hygiene and maladaptation, is excellent and is recommended to the general practitioner as well as to the psychiatrist. The book does credit to the institute from which it emanates.

Landmarks and Surface Markings of the Human Body. By L. Bathe Rawling, M.B., B.Sch. (Cantab.), F.R.C.S. Eighth edition. 8°, cloth, 98 pp., with 36 illustrations. New York: Paul B. Hoeber, Incorporated, 1940. \$3.00.

This little volume offers a handy reference to the surface topography of anatomic structures. Although such treatises are of special interest to surgeons, internists will be interested in the data on the viscera of the cranium, thorax and abdomen, particularly since they relate to physical diagnosis.

The terminology of this eighth edition is revised to conform to the standard B.N.A. nomenclature.

Synopsis of Materia Medica, Toxicology and Pharmacology: For students and practitioners of medicine. By Forrest Ramon Davison, B.A., M.Sc., Ph.D. 12°, cloth, 633 pp., with 45 illustrations. St. Louis: C. V. Mosby Company, 1940. \$5.00.

This book is a well-organized epitome of the subjects mentioned in the title. The first portion is devoted to general principles, and is followed by a description of drugs acting on the various systems, the metals and, finally, the biologicals. Despite its apparent conciseness, a great deal of ground is covered. The small type militates against any sustained reading, and hence lessens its value as a text. For quick reference it should prove very useful.

NUMBER 20

MEDICAL ETHICS*

A Gay Lecture on a Serious Topic

DAVID CHEEVER, M.D.†

BOSTON

IN THESE grim days when the press and the very air bring us news of heart-rending brutality, cruelty and the violation of every moral and ethical principle, it would be an agreeable interlude if even for a moment you could listen to a witty and frivolous talk, but it is probable that all of you have guessed that the adjective in my title is in reality the name of the donor of this foundation—a man decidedly as little gay in personality as he was frivolous in attitude toward his profession. Ethics is defined as the doctrine that treats of the nature and grounds of moral obligation and the rules that ought to determine conduct in accordance with it—the science of right conduct and character. The best way to show you an example would be to transport you on a magic carpet to the world of fifty or sixty years ago and introduce you to Dr. Gay, so that you might walk the wards with him, see him with his patients in office, hospital or home, or listen to him in court or at a legislative hearing. Would that I could paint a picture of him!

George Washington Gay was born in New Hampshire in 1842 of what I like to consider aristocratic lineage—that is, he was the descendant of an English yeoman who came to Massachusetts Bay in 1630. His parents were farmer-folk; he had only a country school education. Perhaps he wished to be a doctor because he had watched the fatal illness of a well-loved sister. After his father's death, he apprenticed himself to a local physician to earn a little money, borrowed more, and went to the Harvard Medical School. Undoubtedly in 1864 he "walked the wards," as the expression was, of the Boston City Hospital in the year of its foundation; he became one of its earliest surgical house officers and was at once

appointed to the newly established Out-Patient Department—thus beginning a lifetime service. With intelligence, courage and an accurate knowledge of anatomy, and inspired by the dawn of the Golden Age of Medicine, he became an accomplished surgeon. He ligated successfully the subclavian, innominate and common carotid arteries, which is testimony to his prowess appropriate to those times. He lectured on surgery, and his students have not forgotten such terse epigrams as: "Every sprain of the wrist is a Colles fracture, every contusion of the hip is a fracture of the neck of the femur, until proved otherwise."

Having no children, perhaps Dr. Gay was the more completely absorbed in promoting the happiness and success of his students and colleagues. Little that was good which needed encouragement—little that was wrong which needed correction—escaped him. As he played a part and later watched the actors on the medical stage, he saw with regret that some of them violated certain moral obligations and rules of conduct pertaining thereto, and thus worked harm to the reputation of the profession and to those who practiced it. And still mindful of the happiness of physicians, he noted their ineptness in business matters and the frequency with which old age, overtaking them after a lifetime of work, found them with but inadequate financial security for their declining years. He therefore created here a lectureship, hoping thus to help them understand these things that were outside their purely professional education. And so it happens to be my privilege to try to carry out a part at least of my old friend and teacher's wish. We might dismiss the matter with the inevitable trite but true statement that behaving like gentlemen and observing the Golden Rule would prevent all ethical blunders. Most of us, however, need a more explicit warning of the pitfalls and perplexities that lurk in the peculiar

*A George W. Gay Lecture on Medical Ethics, presented at the Harvard Medical School, February 13, 1941.

†Associate professor of surgery, emeritus, Harvard Medical School; consulting surgeon, Peter Bent Brigham Hospital.

situations created by the practice of medicine, a fact that has been recognized since Hammurabi, emperor of Babylonia, through the School of Hippocratic physicians, down to the present time. Most organized bodies of physicians have promulgated codes of ethics: that of the American Medical Association, printed as a booklet for distribution, is quite long and explicit, whereas that of the Massachusetts Medical Society deals in its three hundred words with the broadest general principles. Inevitably the manners and social attitudes of the physician are related to the ethical customs, which in turn are interwoven with important problems inherent in the art as distinguished from the science of medicine. These things cannot be taught; the human soil in which flourish the instincts and principles of right conduct was bequeathed to you by your forebears and cultivated at your mother's knee and by your father's side through the years of infancy, childhood and adolescence; if it is not fruitful it is too late now to alter its chemistry, but the vines that spring from it may still be cultivated and the tares uprooted.

It is convenient and conventional to think of the relations of the physician in three categories,—with his patients, with his fellow physicians and with society at large,—yet evidently these are closely related. Mention of them, however, helps a little to clarify an inquiry.

Medicine is certainly a learned, and is usually spoken of as a liberal profession, meaning by liberal, a profession controlled by no narrow doctrine, but receptive to any true advance from any source, whose professors share with each other and with the world their discoveries and methods without thought of deriving from them exclusive personal profit. Thus there is a fairly clear distinction between such a profession and a commercial business or trade, although this has become less clear since business has been touched with the magic of academic edict as "the newest of the professions," and medicine has been commercialized by some of those who practice it. Nevertheless, it is not unreasonable to think of business as primarily concerned with making a profit from its transactions, and of a liberal profession as primarily concerned with rendering service to society, with personal profit as a means to an end rather than the chief objective.

Thus, "a spirit of competition considered honorable in purely business transactions cannot exist among physicians without diminishing their usefulness and lowering the dignity of the profes-

sion." Such competition is I think in two ways: directly by effecting self the practice of others, and advertizing.

Thus is raised the question of proprietorship a physician has vice versa. Formerly, when the rule and specialism the communities were smaller and socially, the physician had his patient attended from birth to death and mutual loyalty. Medical science was one doctor was likely to know as another, and the relief of the patient was owing as much to understanding and confidence by the actual application of scientific adays the advent of specialism question in the patient's mind is the right man to treat the complaint. We all know that is a dispensable way in which science has been advanced; we also know particular problems in some field and solved by special study, and when perfected, many of these patients confidently returned to the general practitioner. If disadvantage overemphasis on specialism, it is the fault of the medical profession partially educated in medical journalism to a point where and without a corresponding acquisition and common sense, demand experience of my own will illustrate the contraction of the fast well known but uncommon when the deformity causes happened that the relief of the extensive, radical dissection gave much better results than operations, interested me and satisfactory results, on the few my way in hospital and private less these palms were exhibited in my community, for on more than with complaints within my family especially abdominal surgery commend a surgeon, and when their condition was one that I operate on, I was greeted by a rejoinder: "Why, I thought you were in hands and crooked fingers to make a living on Dupuytren's

Let us try to be specific about this matter of the proprietorship of patients. It is fundamental that a patient has an inalienable right to consult any physician he chooses, with that physician's consent. Any ethical customs that seem to deny this are based merely on principles of courtesy, consideration for the feelings of others and the real advantage of the patient himself. Clearly, if a doctor has, for years been the trusted adviser of a family group, and has thus become familiar with the physical, nervous and mental reactions of its members, he is likely to be able to treat their illnesses with especial skill and sympathetic understanding. Clearly, if a doctor is in actual charge of a continuing illness, the sudden substitution of another physician will interrupt continuity of treatment and lose the advantages of personal knowledge of the earlier phases of the disease. Moreover, it is inevitable that were a doctor subject to dismissal at the caprice of his patient, he could not possibly feel the interest that springs from loyalty and a realization of appreciated service. Thus we can understand the medical ethic which decrees that "except in case of pressing emergency a physician should not consent to take charge of the patient of another physician," and in case he does so, should return him at the earliest opportunity. What, then, becomes of the inalienable right before alluded to? Simply this: the physician called to take charge of the patient of a brother practitioner should insist that the patient himself notify the other doctor of his dismissal, he would be wise also to have, if possible, a friendly talk with him by telephone or in person.

The laity often complain that they are estopped by medical ethics from having the physicians whom they want. As will be seen from what I have just said, all that doctors ask is courteous treatment and the assumption by the patient himself of full responsibility. The best solution of the patient's desire to have other advice is the consultation. Every physician worthy of the name should welcome a consultation with another authority whom he respects; he has a right to refuse to call a man who does not meet this requirement. The conscientious doctor will always ask for a consultation if he is in doubt about the plan and course of treatment, he will be wise if he also does so whenever he detects a wavering of confidence on the part of the patient or his family. I consider it wishful thinking to say that the asking for a consultation by a physician may not plant doubt and anxiety in the patient's mind, but it need not do so if he is a person of sense who sees in it the act of a broadminded physician who will leave no stone unturned to combat his disease. Much depends, of course, on the

tact and attitude of the consultant, whose suggestions must not connote criticism of what has been done; it is perfectly possible to change a diagnosis and prescribe a different course of treatment if the matter is approached with tact and consideration for the feelings of all concerned. Sometimes, however, it is inevitable that the patient—or more probably his friends—will insist that the consultant take over the care of the case. Positively, this may not be done without the full consent of the attendant, practically, it is best that it be avoided, if possible. Perhaps the dilemma may be solved by an agreement to see the patient again at suitable intervals without the formality attending a first consultation; sometimes it has been thought best to agree on another physician to take charge. Everything must be done, consistent with the patient's welfare, to prevent the conscientious physician who is willing to call a consultant from thereby losing his patient.

Let us return to a comparison of the customs of a liberal profession and a commercial business, especially in the matter of advertising. It is not necessary to invoke the authority of the late P. T. Barnum, supershowman, as to the secret of his success, to prove that advertising will bring material reward, but it needs no argument to prove that a liberal and learned profession would lose its dignity and repute if it adopted such methods. Advertising makes its appeal through the senses to the emotions by methods of persuasion, exaggeration and overstatement sometimes bordering on deception. The time-honored viewpoint of the leaders of our profession that a physician should be advertised among the laity only by the inevitable spreading of good reports about him by his satisfied patients, and among his colleagues by his participation in medical meetings and his contributions to medical periodicals, which give a perfectly proper account of what he is interested in and what he is doing, is still sound. The grosser forms of publicity need not be enumerated. Professional cards should be sent only to colleagues and bona fide patients and published only in medical journals, an exception being the custom of placing a card with name, address and specialty in newspapers of cities with large foreign-born population to help those who are handicapped by language difficulties in finding a doctor. No circular or statement descriptive of a physician's methods or achievements should be published or circulated. Of late years the daily press has succeeded in creating and whetting in the public an insatiable appetite for medical news, and boards of health, educational institutions and private groups have adopted as their duty the education of the people in medical matters. In this com-

petition for acceptable news to fill their columns, the papers report medical lectures, publish excerpts from medical periodicals and importune physicians to grant interviews and write articles on purely medical topics. It cannot be denied that if Dr. John Doe, of 10 Harley Street, who is a specialist in cardiology, gives a popular lecture on heart disease before some fraternal association and their ladies, which is reported in the morning paper, he will have secured a most effective advertisement at the expense of his more conservative and less vocal colleagues. To inform the public properly in regard to health matters, without undesirable publicity for the physician, is a delicate matter. Such material should be supplied by medical columnists who are not practitioners, or by the secretary or a committee of a medical society, or at least under the aegis of an educational institution. It is an age of publicity: you probably cannot keep out of the newspapers but you can discourage and refuse to have a part in anything that through its quality as an advertisement tends to give you an advantage over your colleagues.

One subject in connection with ethics that seems scarcely worth discussing among gentlemen is the inviolability of the confidential relation between patient and doctor. The physician on occasion may have to inquire about the most intimate matters,—the patient may have to bare his soul, if his ills are to be helped. The revealing of such things to a third party almost inevitably leads to the dissemination of gossip, false rumors, notoriety and unhappiness, and if traced to its source, destroys the confidence of the patient in his physician. Such situations are more apt to arise in small communities where people are well known to each other than in urban practice. Two exceptions to the obligation of professional reticence exist: in a Massachusetts court of law there is no such thing as a privileged communication, and a doctor may be subpoenaed and required to tell the facts in his possession; the second exception is in connection with communicable diseases in which silence may jeopardize the public health or the health and happiness of an innocent person. A simple statement to the patient of your plain duty in the matter will convince him that he must adjust it, or allow you to, in the way best for the public interest.

No question on the fringe of medical ethics is more troublesome than the remuneration of physicians. There is no accepted scale of fees, the nearest being the fee tables agreed upon by some local medical society for local application only, and hortatory rather than obligatory on its mem-

bers. There was once a Boston Medical Society, which issued such a table, now long obsolete. Actually at one extreme stands the old-fashioned family doctor in the country, whose fame is sung in fiction, biography and poetry; who sent no bills, kept no books, collected a little cash but a great many commodities on which he and his family lived. His expenses were very small. How much he influenced the course of the diseases which he treated is problematical, but when he died the whole countryside mourned his passing. At the other extreme stands the surgical specialist who may charge what the traffic will bear. Our local code says that "with the understanding and consent of their patients beforehand, physicians may place any value upon their services deemed proper."

But who shall decide what is to be "deemed proper"? There is no regulating body, the nearest approach being the various types of sickness insurance and group medicine schemes that are springing up over the country. The lay public sometimes protest that they cannot understand the necessity for the sliding scale that generally obtains under our free institutions, but the explanation is simple enough. On the one hand the physician, being a liberal-minded man practicing an altruistic profession, is traditionally glad to donate his services to the poor, to lessen his charges to those of small means; to make full charges only to those who can pay them without being crippled thereby. It was a tradition in old New England that a doctor should expect and plan that at least two fifths of his work was likely to be unremunerative. On the other hand the physician has a right to expect to earn a decent living; he has spent the best years of his life and many thousands of dollars in preparing himself; his earning power amounts to little before he is thirty; if in city practice, he is likely to find himself shelved by an age-retirement hospital ordinance at sixty-three, and there is always the intervening threat of coronary occlusion. Moreover, his overhead expenses for office and instruments of precision for diagnosis or therapeutics are vastly greater than his father's were. To support his family and provide for old-age security on the precarious collection of small fees certainly demands great industry and good health, and justifies the charging of generous sums in appropriate cases. And who can say what a physician's services are worth? Apologists for huge fees say that there is no limit to the value of the successful conduct of a case of lobar pneumonia, or for saving a life or for making it tolerable by a surgical operation. No doubt a millionaire would agree that he would give nine tenths of his fortune if it were necessary to save his life, but

the point is that it is not necessary, since there are probably dozens, scores or hundreds of other physicians available who could render the same service. An infinite number of workers, some conspicuous and some humble, daily do work on the skillful performance of which depend the lives of countless citizens: the engineer, the engine driver, the mechanic who repairs the steering gear. It is impossible to compute the dollar value of human life and use it in determining fees.

What is the objection to charging fees if they may be collected? One reason is, of course, that the fee may be a financial burden that makes the doctor's services more of a misfortune than a blessing. A second is that it may become the subject of dissatisfaction, remonstrance or even litigation, which destroys the mutual confidence between physician and patient, and the gratitude of the latter toward him who should be his benefactor. A third is that the report of a large fee imposed travels far and wide, like any sensational bit of news, and creates in the public at large the conviction that doctors are overpaid, mercenary persons whose services are not within the reach of people of moderate means. Thus are the public turned toward free clinics. A peculiarly unlovely form of overcharge might be called "raiding the estate." Some physicians, if their patient has died, seem to consider that so long as the deceased has no further use for his property, it is proper to make a large charge to be paid by the executors, whereas in fact those formerly dependent on the deceased may find themselves seriously embarrassed by the loss of his earning power. But the chief argument against huge fees is a spiritual one: the degradation of the physician's ideal from that of service to that of selfish personal advantage.

I recommend a simple way of dealing with this question, namely, the direct approach, which ought not to be criticized on the ground of poor taste or lack of dignity, because the freeing of the patient so far as possible from financial worry is often an important factor in his recovery. Except when the patient and his resources and attitudes are well known to you, ask him frankly if he would like to discuss the probable cost of your services. If he says there is no need, well and good, but nine times out of ten he will welcome the suggestion. Then name a suitable maximum charge, which you consider your services to be worth, and say that you are accustomed to scale down your charges in case of need to a certain irreducible minimum, which you are justified in maintaining, because if it is not worth your while to work below that figure, the patient's needs may be

provided for by referring him to a younger but fully competent man or, if necessary, to a free clinic. Often it may be acceptable to calculate with him the total cost of his illness, including hospital care, nursing and incidentals, and on occasions I have promised that the total cost shall not exceed a certain sum, with the implication that my fee would be proportionately less in case other expenses were unexpectedly large. These methods in my experience have brought satisfaction and a minimum of disputes. The plan adopted by some busy doctors, or especially by highly organized clinics, of having professional charges entirely arranged by a paid fiscal agent seems open to objection on the ground that it cannot be a satisfactory substitute for the sensitive perceptions of a conscientious physician; it is enough to remind you that the cashier is primarily a business person.

Here it is appropriate to say a word about collecting the money you have earned. If cash is offered, you had better accept it. For most services you will send a bill at a convenient time, or on the first of the month, or quarterly. It should be itemized in a broad way,—the inclusive dates, the number of visits, the special services,—so that the patient will know what he is asked to pay for. If monthly or quarterly reminders and a personal letter or two are ignored, you must decide whether to let the matter drop or to employ a collecting agency or your own lawyer: If an agency, you must satisfy yourself that the methods it proposes to employ have your approval. The threat of legal action is implied in any measures taken by an agency, and although a letter from an agency or lawyer may be sufficient, it is only too likely that further steps—attaching a patient's property or a lawsuit—may be advised. I strongly advise against either of these measures; although justified by rules of strict justice, they tend to identify the rendering of medical service with the sale of goods, they inevitably lead to the permanent loss of your patient, to the spreading of ill reports about your mercenary attitude, and not infrequently to the filing of a countersuit for malpractice by an angered and dissatisfied patient. But once in my life have I threatened suit for payment, and that was when I was virtually accused of homicide by the frenzied parents of a child whose attack of acute appendicitis they had neglected; I recovered a small fee, which was poor compensation for my expenditure of nervous energy, and I could not be sure that the parents' moral outlook had been helped.

In connection with what has been said about the fallacy that a physician has a proprietary interest in his patients, it should be added that, con-

trary to an opinion widely held among the laity, you are under no legal obligation to undertake the care of a patient. In a pressing emergency there is, of course, a compelling moral obligation to respond, and a case once undertaken may not be relinquished until it is placed in other competent hands. If you are called, especially at night, by a person unknown to you, to a distant locality, it is well to act with caution; a good expedient is to recommend that a local physician in the neighborhood be called, and say that you will respond if he finds it necessary to ask for your assistance—for this purpose make it a practice to know the names of reliable doctors in the various sections of your city. If you go without this precaution, leave your watch and wallet at home. There is another aspect of night calls, however: there seems to be a tendency among some practitioners to shirk the tiresome and onerous things. Not long ago one of those rarely fortunate men who lived at a period and in a locality that permitted him to do general practice and cultivate a specialty as a hobby told me that he was called at night by a lady whose family he had formerly attended for many years, who apologized for calling him to come to see her grandchild, who seemed acutely ill. "But my dear Mrs. Blank," he said, "you know I am eighty-three years of age, and that some time ago I turned you over to my young friend, Dr. John Doe. Why do you not call him?" "I have just done so," she replied, "and he said that he does not go out nights." The old doctor assured her that either he or Dr. Doe would be over as soon as possible, and it is scarcely necessary to say that a telephone call from the older to the younger practitioner brought relief to Mrs. Blank's anxieties.

It is surely sound ethics that everybody who applies to you as a sufferer seeking relief must be enabled to obtain that relief. I have tried to make it a point of honor to see that anyone who came to me for advice and whom, for one reason or another, I could not handle should be definitely placed in the hands of a competent colleague or recommended to an appropriate clinic—such reference being accomplished and assured, if possible, by personal communication, and the patient being told to let me know if he is still at a loss.

A problem that has always plagued doctors and about which there is some difference of opinion is our attitude toward the quasi-medical cults. It is safe to say that there always have been and always will be those who profess to heal the ills of mankind by methods based on a mistaken all-inclusive doctrine rather than under the guidance of scientific knowledge. Much as we pity those unfortun-

ates who are the victims of these cultists, it is a mistake to castigate, scorn or hold the latter up to ridicule, since experience shows that this avails but little except to excite the suspicion of intolerance, jealousy and the existence of a "medical trust." This is especially true, of course, in cults founded on religious belief, in which criticism may profoundly wound the spiritual nature of those who profess them. But there is another side. If we subscribe to the doctrines so well expressed in our code that "physicians should encourage sound medical learning and uphold in the community correct views of the powers and limitations of the science and art of medicine, and should clearly maintain the distinction between legitimate medicine and quackery," it is difficult to see how we can honorably consult with a cultist over a medical problem. A consultation implies a common basis of belief. Would it be profitable for a scientific physicist to confer about a subject in his field with a man who believes that the earth is a flat disk? And yet there is said to be much consulting between regular physicians and cultists, which cannot fail, it seems, to dignify and strengthen the cultists in the eyes of the laity. "But," you will ask, "are not the interests of the patient paramount, and can I not help him by consulting with his cultist adviser?" Certainly his interests as a sick man are paramount, and your consultation may help him, though under the circumstances, not with certainty. The way out of the dilemma that I suggest is to agree to the consultation on the condition that you be permitted to explain to the patient that you do not subscribe to his adviser's doctrines and fear that your reliance on medical science will not be acceptable to him. If the patient and his friends are anxious enough, they will insist on having you, but your reputation among the other group as a desirable consultant is not likely to grow.

When my crusading spirit was stronger than it is now, I sometimes tried to bring a lost sheep back into the fold, always with disappointing results. On one occasion I was consulted by a lady who some months previously had discovered a small lump in the breast. According to her story she consulted a practitioner of a cult employing manipulative therapy, who stated that he found an abnormal condition of the fourth dorsal vertebra at the same horizontal plane as the breast lesion, for which it was undoubtedly responsible. Three times a week for some months he manipulated the spine, and at the end of each visit he did something to the breast lesion that I was given to understand by him was not rubbing or massage but something involving very special skill because

it was done with the heel of the hand. When I examined the patient, there was presented a still small primary tumor showing every characteristic of a carcinoma, but the striking thing was the presence of involved nodes in the axilla and a number of small metastatic lesions in the skin surrounding the tumor—something that I have not seen before or since in so early a case and that must have been due apparently to the manipulation. A radical extirpation with skin graft was done, with the inevitable sequel some years later. I found it hard to believe that this practitioner would not be aghast when brought to full realization of what he was doing. In a friendly and conciliatory spirit I invited him to witness the operation; he did not appear. I then invited him to come to the laboratory where the fresh specimen was being preserved so that it might be demonstrated to him by Dr. Wolbach. In answer he wrote a letter saying, among other things, that he guessed that if Dr. Cheever had cured without mortality by operation as many fibroid tumors of the uterus as he had by his special manipulation of the spine, he would not have such an ill idea of the methods of the cult. Feeling that this man was a menace to society, I brought the facts to the attention of the authorities, who, after a hearing, admonished him! I like to believe that I accomplished something in this case: perhaps there was satisfaction in hearing that word went forth among the professors of that particular cult to "ware Cheever!"

A practical matter which should be mentioned relates to the attitude and duties of a physician as a witness in court. You can be subpoenaed like anyone else and must testify to facts in your possession; if you are asked your opinion or a hypothetical question, you have a right to insist that you be qualified as an expert witness. It has before been stated that no communication between doctor and patient is privileged in a Massachusetts court. Expert testimony in the innumerable cases in which a medical opinion plays a part should be an opportunity for the physician to render important public service, but as a matter of fact, since he is almost always called by counsel for the plaintiff or defendant, there is strong incentive for him to become a medical advocate, and the limitations of the rules of evidence and the ingenious harassment of the cross-examination often make him feel that he has actually been unable to say exactly what he wanted. A special perplexity confronts the physician when he is asked to testify for the plaintiff in a suit for malpractice against a brother practitioner. So loth are most doctors to do this that there is complaint

on the part of lawyers that it is next to impossible to get a doctor to even averred that he would not punish one member for testifying against another. There is of course no ground for such a statement. Organized medicine simply requires that in this as in all other professional duties its members be guided by strict honesty and fairness. As a matter of fact, most cases of malpractice that are tried in court have little or no merit and are simply efforts on the part of a patient and his lawyer to turn an unavoidable misfortune to pecuniary advantage; the few cases in which the defendant physician is legally at fault are usually settled out of court. A physician asked by a lawyer to testify against another, should examine the records and inquire into the circumstances with the greatest care, should go over the matter with the defendant physician and consider carefully what he would have done if he had been placed in the defendant's position, and should convince the attorney that he proposes to be uncompromising in his refusal to permit himself to become an advocate. It is almost unbelievable that some physicians will lightheartedly agree with a lawyer friend to testify in court and answer hypothetical questions without having done any of these things, when the price of the loss of the suit by the defendant physician may be his reputation and many thousands of dollars. Such action on the part of a member of a medical society is indeed ground for critical inquiry by its officers.

Is it imperative and wise, or unwise and wrong, to tell the patient the truth about his disease and its prognosis? This question arises of course almost solely in cases of cancer. There are three types of people to be considered: first, those of mature age who ask for the truth in such a manner as to leave no doubt of their sincerity—these people are exercising their personal right to information and should be told with such mitigations as are possible; secondly, those who ask in a halfhearted way and do not press the question and in the circumstances of whose lives there appears to be no cause to feel that the knowledge is needed for any reason; and finally those who do not ask. How foolish it would be to tell a woman—a cancerphobe as most women are—who has undergone a successful operation known statistically to promise 75 per cent of five-year cures, that her disease was cancer! How cruel to tell a woman ignorant of her hopelessly malignant internal disease and happy in her fancied security, if there are no vital issues to be settled before the end. There is no disagreement, I think, on the rule that one nearest and most responsible

relative or friend should be told the exact situation as you see it, again with what mitigation and exceptions you can honestly make; then tell no other questioners, but refer them to the confidant whom you have chosen. Whether or not an actual prevarication is permissible must be left to your own conscience, but it is rarely necessary, since tact and evasion will usually suffice, but perhaps, like me, you cannot see the fine distinction between these courses.

Rereading what I have written, the same thought occurs to me as did when I somewhat reluctantly agreed to undertake this lecture, namely, that these problems of medical ethics seem trivial and hardly worth considering while catastrophic forces of greed and cruel brutality are tearing to pieces the world of democratic culture in Europe and Asia, and even more widely the formerly accepted canons of morality in social behavior and in the economic field are being questioned and shaken to their foundations. But it is precisely at such a time that one must hold fast to what is good. Even now our profession, in company perhaps with but one or two others, motivated by as pure ideals as are possible to earthly man, is pursuing its self-appointed destiny of relieving illness and pain wherever possible. It is a noble profession in its possibilities for service, but its nobility will be but a name unless it is practiced nobly. Never

were the responsibilities greater of those who now practice and teach it and of you who are being trained to the succession. The chemical and physical agents that science has placed in our hands are powerful for harm as well as for good, and constant study is the price we pay for the ability to render our patients the service that is their due. Attacks on our profession by social demagogues, the general spirit of questioning of and revolt against authority, which is rife in the community, sometimes the little knowledge that is proverbially so dangerous, which is fed to the people by many sources—all these tend to undermine the confidence of the public in the medical profession, and every candid, thoughtful man among us knows that the selfishness, intolerance and greed of a few of our members are contributing to the same result. At our school here you have gained factual knowledge, clinical experience and an appreciation of the scientific method, but it would be a sorry thing indeed if you had not found and admired in your teachers those qualities of the heart and spirit that are more potent than science itself to make our profession a noble one. During forty-four years I have lived and had my being among our teachers and students, and I think that I can assure the shade of Dr. Gay that we are carrying on!

193 Marlboro Street

THE MENOPAUSE: A HORMONIC AND THERAPEUTIC STUDY*

CHARLES H. LAWRENCE, M.D.,† AND ADRIAN C. MOULYN, M.D.‡

BOSTON

ALTHOUGH repeated investigations¹⁻⁴ have identified the changes in hormone balance that accompany cessation of menstruation at the menopause, and have shown that available hormone extracts are effective in compensating this dyscrasia, the treatment of the menopausal patient is still a vexatious and often unsatisfactory task, and there is no unanimity concerning the indications for treatment, hormonal or otherwise, during the so-called "change of life." Novak⁵ states that the majority of women need no organotherapy whatever during the menopause, whereas Hawkinson,⁶ from a study of 1000 cases, believes that "menopause without distress is unusual." More specifically, Frank, Goldberger and Spielman⁷ carried out an enormous number of assays of estrogens and gonadotropins in the urine and blood of menopausal women, and found evidence of anterior pituitary overload in the blood in less than 50 per cent of such patients. Geist and Mintz⁸ call attention to the lack of correlation between the excretion of these hormones and the presence of menopausal symptoms. Albright⁹ concluded from his careful study that the vasomotor symptoms of the menopause are due directly to an overproduction of prolactin, and that when this overproduction is controlled by estrin therapy, those symptoms are either markedly diminished or disappear, whereas Frank, Goldberger and Salmon¹⁰ believed that no permanent relief results from estrin treatment. Pratt and Thomas⁹ report that in a series of 100 patients relief was obtained about equally from treatment with estrogens, phenobarbital, lactose, injections of oil containing no estrogen and bromide.

These apparently conflicting opinions leave "confusion worse confounded," unless they can be explained by further study of the menopausal syndrome. At the outset of such a study, several established facts must be recognized, the most important of which is that the syndrome in question is almost unique, since the diagnosis is usually made, not by the physician, but by the patient, and since the symptoms are almost entirely subjective, protean in character, and not related to any demonstrable physical signs. It is quite

possible that more than one factor is responsible for the menopausal syndrome, and the great variance of the symptoms encountered in different patients is strong presumptive evidence of their multiple causation. Further study is still needed to determine the correlation between the hormone assays, the predominant symptoms and the responses to different forms of treatment in a significant number of patients.

To that end, this report includes only patients for whom the above data were satisfactorily determined. On admission to the clinic, each patient was examined thoroughly in the medical department before being referred to the Endocrine Clinic, where an additional history of the duration, severity and type of symptoms was obtained, and the hormone assays and other indicated studies were carried out. In taking the histories, an effort was made to get a spontaneous statement from each patient concerning her symptoms, because it was believed that this method would help to determine their relative severity and importance. The presence or absence of typical symptoms not mentioned by the patient was then determined by direct questions. For an initial period of approximately two weeks, or until the hormone assays of the urine were completed, every patient, irrespective of the type of symptoms she complained of, was treated with injections of sesame oil or with a sedative—bromides or phenobarbital. When the assays were completed, the patients with positive prolactin tests were given injections of estrin in oil[§]; the usual dose was 10,000 rat units two or three times a week, but varied somewhat from patient to patient. Those with negative tests continued the initial therapy until its effect could be determined. If no improvement occurred, one of the other forms of treatment was substituted. In no case was the patient informed of the change from sesame oil to estrin in oil, or the reverse. When it seemed advisable and practicable, hormone assays were repeated during and at the end of treatment.

By this method it was possible, in 100 of the 131 women studied, to compare the results of the three forms of treatment in each patient, and in most cases to correlate both symptoms and results of treatment with the hormone assays. For convenience, symptoms were divided into three groups:

*From the Endocrine Clinic and Laboratory, Boston Dispensary.

†Assistant professor of medicine, Tufts College Medical School; physician-in-charge, Endocrine Clinic, Boston Dispensary.

‡Formerly, junior assistant physician, Medical Department, Boston Out-patients, and research assistant, Tufts College Medical School.

those apparently associated with unstable vasomotor control, those obviously due to nervous instability, and those labeled, for want of a better term, "metabolic symptoms." In this last group were placed such uncommon symptoms as marked physical exhaustion not associated with nervous depression, and arthralgia without demonstrable joint disease. The patients were divided into two groups: those whose urine gave a positive test for prolان, and those whose urine contained no demonstrable prolان. No attempt was made to group patients on the basis of the estrin determinations, because no correlation could be established between a patient's symptoms and the presence or absence of small amounts of estrins.

The patients were therefore separated into two groups, according to the results of the urinary prolان assays, and the same criteria were applied to each. The groups were practically identical in size: 48 patients yielded positive tests for prolان, whereas negative tests were obtained in 52. It is perhaps significant that there was a considerable difference in the average age of the two groups—44.0 years for the positive, and 49.5 years for the negative. Eliminating all patients in whom menopause had been artificially induced did not alter the difference significantly: the negative group still exhibited 5.3 years' seniority.

A similar difference was found in the duration of the symptoms. The average duration in the patients whose urine yielded a positive prolان test was 2.4 years, in those with negative tests 3.2 years. Excluding induced menopause, the averages became 1.4 and 2.5 years respectively. It is, of course, impossible to accept as accurate a patient's statements about the duration of symptoms, but the error was probably equal in each group and was consequently not significant. Even in patients in whom menopause had been induced by surgery or irradiation, and who therefore could be definitely dated, the differences persisted practically unchanged: 3.8 years for the positive group, and 4.9 years for the negative. The greater average age, and the longer duration of symptoms suggest that the women who composed the prolان-negative group may have passed through the endocrine disturbance characteristic of the menopause, and that they may have achieved the hormone balance characteristic of postclimacteric, symptom-free patients.

This possibility acquires practical significance when the predominant symptoms of the two groups are compared. In 81 per cent of patients in whom the prolان test was positive, the vasomotor symptoms—flashes, headache and giddiness—dominated the picture, and the patients either did not complain of psychic or nervous disturb-

ances or attributed them to the irritation of the constantly recurring and often severe vasomotor symptoms. Many stated that if they could be rid of the latter, they would be perfectly well. In 61 per cent of the prolان-negative patients, on the other hand, the presenting symptoms were almost purely characteristic of a psychoneurosis, and the vasomotor symptoms dominated in only 15 per cent. In the remainder, vasomotor and psychoneurotic symptoms were so inextricably interwoven that it was impossible to weigh them satisfactorily. All such patients, however, gave a history of nervous instability that antedated the menopause by many years. It seems fair to conclude, therefore, that they represented a combination of endocrine and nonendocrine instability in which it is impossible to evaluate satisfactorily the role played by either condition.

If the two contrasting clinical pictures just outlined depend on different hormonal situations, their response to hormone treatment should differ sharply. An analysis of the results of treatment showed that 90 per cent of the prolان-positive, vasomotor group improved definitely with adequate estrin therapy, whereas only 25 per cent of the prolان-negative, psychoneurotic group were similarly benefited. The converse is also true, since only about 20 per cent of the former were helped by sesame oil or sedatives, whereas approximately 80 per cent of the latter improved very definitely during treatment with one or the other of those preparations. Inasmuch as the change from sesame oil to estrin injections could not possibly be detected by the patient, the error due to a possible psychologic factor seems considerable.

From these figures it seems justifiable to construct a working hypothesis concerning women who seek relief from symptoms that they ascribe to the menopause. Their symptoms comprise two more or less distinct groups. In one they are preponderantly those of vasomotor instability, are associated with an excess of prolان in the urine and are relieved by treatment with estrogenic extracts in quantities sufficient to cause its disappearance from the urine. This conclusion is in agreement with the work of Albright.⁴

In the other, slightly larger group, psychoneurotic symptoms predominate, prolان is rarely found in the urine, and treatment with estrogenic extracts fails to give relief in a significant majority of cases; sedatives and psychotherapy are as a rule more effective. On the average, these patients are 5.5 years older than those in the contrasting category, and have had their symptoms over a year longer when they present themselves for treatment. These differences suggest that they have passed

through the period of endocrine imbalance, which from the point of view of endocrine therapy defines the actual menopause, and that they are more properly to be regarded as having reached the postmenopausal or senescent stage of pituitary ovarian reciprocity. Since hyperprolactinism cannot be the cause of their nervous instability, some other explanation must be found. That explanation, we believe, lies partly in the psychic and nervous make up of the patient, and partly in the fact that for centuries women have been led to expect nervous disturbances, as well as hot flashes, as inescapable features of the menopause. The psychoneurotic symptoms, therefore, represent a conditioned reflex activated by the obvious cessation of menstruation, and often aggravated, by other coincidental stresses. It must always be remembered that hyperprolactinism occurs in only a small fraction of menopausal women, the majority of whom "need no organotherapy whatever," since "their symptoms are either slight, or are controlled by reassurance, avoidance of stress, physical or mental, or perhaps by simple sedatives."

Between the vasomotor and the psychoneurotic groups, and exhibiting various combinations of the symptoms characteristic of each, lies a third and smaller group in which symptoms of both vasomotor and psychoneurotic instability are about equally prominent. The patients composing this group are most difficult to help. Careful questioning, however, will usually disclose the fact that their nervous instability antedated, although it may have been further activated by, the menopause, and that it will respond better to simple psychotherapy and judicious use of sedatives than to estrogenic therapy. The latter, however, may be useful in relieving them of vasomotor symptoms. In this group, hormone assays are essential to correct treatment, since the hormone status of the patient can be determined in no other way.

CONCLUSIONS

In only a small minority of women are the symptoms associated with "the change of life" sufficiently severe to compel them to consult a physician.

A test for prolactin in the urine was positive in only 48 of 100 women admitted to our clinic because of the severity of their menopausal symptoms. In 81 per cent of this group the symptoms were preponderantly those of vasomotor instability, and 90 per cent of these patients were definitely benefited by adequate treatment with estrin.

In the remaining 52 per cent the test for urinary prolactin was negative. Treatment with estrin caused improvement in only 25 per cent of the patients treated, whereas simple psychotherapy or sedation brought relief in over 80 per cent. The patients in this group were older, and had had symptoms significantly longer, than those who were benefited by estrin treatment.

No relation was evident in either group between the presence or absence of estrin alone and the character or severity of symptoms.

A predominance of vasomotor symptoms in a menopausal woman is suggestive of an overactive prolactin production, but treatment with estrin should not be instituted until urinary assay proves that prolactin is being excreted. Coincidental estrin determinations are interesting but not essential.

If treatment with estrin is indicated, it should be given in effective amounts. Failure to relieve the vasomotor symptoms in a patient with positive prolactin assays is probably due to insufficient dosage. The effective dosage in any patient is an individual equation.

ALCOHOLISM: SOME CONTEMPORARY OPINIONS*

MERRILL MOORE, M.D.†

BOSTON

A SYMPOSIUM on alcoholism was held in Philadelphia on December 27, 28 and 29, 1940, during the annual meeting of the American Association for the Advancement of Science, sponsored by the Research Council on Problems of Alcohol. Six special sessions were closed by a public meeting on the evening of December 29. All sessions were well attended by physicians, psychiatrists, sociologists, lawyers, members of the clergy and others.

The program was planned to cover all aspects of the alcohol problem, beginning with physiologic and chemical considerations and the clinical aspects, to which the first day was devoted. The neuropsychiatric features and the treatment and prevention of alcoholism were the subjects of the second day. The third day was devoted to social and legal problems. The final address, in addition to the original contribution of Dr. Abraham Myerson, summarized and discussed the entire field and pointed out several trends that would affect the immediate future of research on alcoholism.

In his introductory remarks on the morning of December 27, Dr. Winfred Overholser, superintendent of St. Elizabeths Hospital, Washington, D. C., described the nature and extent of alcoholism. He cited illustrative statistics, and, as one of the founders, he outlined the history and aims of the Research Council on Problems of Alcohol, as well as the purpose and plan of the symposium. Dr. Overholser stated:

Although the enlightened of today recognize excessive and prolonged use of alcohol as a disorder of conduct, a disease, in some instances at least, amenable to treatment, it is a fact that throughout the United States, with the exception of the large cities, practically the only institution in which an acutely intoxicated person may be cared for is the local jail. Drunkenness in a public place is still a penal offense and, in all too many cases, it is the rule to give a short sentence to the person who is brought before the court on a charge of public intoxication, even though the judge, the court attachés, and the jail officials realize that release from jail is all too likely to be practically synonymous with further intoxication and further sentence. . . . It is extremely difficult to say just how many alcoholics there are at the present time in the United States. The statistics of arrest indicate that annually well over 100,000 persons are arrested on a charge of drunkenness, about 27,000

on a charge of driving an automobile while under the influence of liquor, and about 27,000 on a charge of disturbing the peace, an offense often associated with over-indulgence in alcohol. In addition, over 4900 persons were committed to mental hospitals in 1938 by reason of alcoholic psychosis and nearly 7600 for alcoholism without psychosis; statistics are not available as to the number admitted to the alcoholic wards of the various municipal hospitals. . . . It is safe to say that there are in the United States probably more than 100,000 persons suffering from alcoholism at the present time. Thus, with tuberculosis, cancer, syphilis, mental disease and infantile paralysis receiving competent and intelligent medical attention, we now have alcoholism as the greatest public health problem at the present time which is not being systematically attacked.

The session on physiologic and chemical considerations of alcoholism, at which Dr. Overholser presided, was opened by a paper on "The Influence of Alcohol on the Alimentary System" by Dr. A. C. Ivy, of the Northwestern University Medical School, who reported a study on the effect of alcohol on the motility of the colon and the secretion of bile. In dogs, he found that alcohol given by any route in amounts sufficient to produce moderate-intoxication tended to depress the nonpropulsive and to augment the propulsive motility of the colon. The latter results were substantiated in human subjects who were given 250 cc. of Bourbon whiskey by mouth. Dr. Ivy believed that these observations provided an explanation for the irregular relief of colonic colic after ingestion of alcohol and the tendency of alcohol to cause diarrhea in certain persons. Dr. Ivy also reported his experiments in feeding 40 cc. of alcohol daily for two days to dogs with biliary fistulas. He found that there was evidence of definite injury to hepatic cells, that there was a distinct change in the chemical constitution of the bile, and that the odor of alcohol was apparent. The cholic acid content was decreased, but the animals became normal within two days after the alcohol was discontinued.

Dr. F. A. Hitchcock, of the Department of Physiology, Ohio State University, reported on "The Alterations in Respiration Caused by Alcohol." He had found that alcohol seems to accentuate normally occurring peculiarities in breathing as well as to produce a more rapid and often shallower type of respiration. In many cases, an increase in the total pulmonary ventilation might be interpreted as a stimulation of the respiratory center

*A report on the Symposium on Alcoholism of the Research Council on Problems of Alcohol at the annual meeting of the American Association for the Advancement of Science, Philadelphia, December 27, 28 and 29, 1940.

†Associate in psychiatry, Harvard Medical School; assistant visiting psychiatrist, Boston City Hospital.

by alcohol. In two out of three subjects, the sensitivity of the respiratory apparatus was decreased to both carbon dioxide and to oxygen lack after taking alcohol. In one case, the subject showed indications of increased sensitivity, which suggests that the reaction of the other two subjects was the result of the brief duration of the period of increased sensitivity, which, if actual, may be of short duration and may be followed by a period of hyposensitivity. The alveolar carbon dioxide tension decreases in the first half hour after ingestion, and then returns to a value equal to or greater than that found before alcoholic ingestion.

'The Hypoglycemic State in Alcoholism' was the title of a paper presented by Dr H D Palmer, of the Institute of the Pennsylvania Hospital. Dr Palmer reported a number of cases in which alcoholism was a prominent symptom; in his study he found that a number of the patients showed an atypical carbohydrate metabolism, as indicated by their sugar tolerance curves. Regulation of the diet tended to correct this condition in certain cases by stabilizing the carbohydrate metabolism and energy expenditure, and resulted in some relief of the symptom of drinking. Dr Palmer's detailed findings were of especial interest not only on account of their relation to alcoholism but also because of their bearing on hyperinsulinism and neuropsychiatric conditions involving abnormal behavior patterns.

Dr Henry Newman, of Stanford University School of Medicine, discussed 'The Problem of Acquired Tolerance to Alcohol.' Prior to Dr Newman's study there were few satisfactory data on acquired tolerance to alcohol in human subjects except for comparisons between the metabolism of habituated and nonhabituated subjects. The hypothesis that delayed absorption of alcohol might be responsible was found by Dr Newman to be inadequate, nor could the possibility of delayed penetration of alcohol into the nervous system serve as an explanation of variations among different patients. Dr Newman and his associates were able to show by experimental techniques that habituated subjects do not metabolize alcohol faster than nonhabituated animals. They concluded that actual tolerance to alcohol, if it can be acquired, must depend on tissue tolerance or on a difference in the behavior of the cells of the central nervous system to a given quantity of alcohol, as compared with similar reactions in nonhabituated subjects.

A paper on 'The Effect of Alcohol on the Electroencephalogram' was presented by Dr Hillock Davis, of the Department of Physiology, Harvard Medical School. This work had been done

in collaboration with the Department of Neurology and the Neurological Unit, Boston City Hospital. Dr Davis, Dr Frederic Gibbs and their associates studied the encephalographic tracings of six men to whom a measured quantity of alcohol had been given (2 cc per kilogram of body weight). Psychometric examinations were made by Mr Lowell S Trowbridge, and blood alcohol determinations were made at intervals throughout the experiment. A spectrum analysis of several of the records by means of the Grass analyzer showed a reduction in energy on the fast side of the frequency spectrum, particularly in the range from 10 to 13 cycles, at relatively low concentrations of alcohol. At higher concentrations of blood alcohol, there were episodes of slow waves (4 to 8 cycles) that intruded into the subjects' characteristic electroencephalographic patterns and appeared in the spectrum analysis as an increase in energy in the corresponding frequency band. The performance on the psychometric tests—particularly the addition of consecutive digits, the reversed-clock problem and the strength of grip—was definitely impaired while the concentration of blood alcohol was at its height (125 to 140 mg per 100 cc) and for an hour thereafter, but became approximately normal in four or five hours. When the patients were clinically sober, the blood alcohol remained elevated and the electroencephalogram was still modified. The poor performance on the psychometric tests was associated with slurring speech, ataxia and emotional changes.

Dr Curt P Richter, of Johns Hopkins University School of Medicine, reported a series of feeding experiments in which the characteristics of alcohol as a food were considered. The study indicated the concentrations of alcohol that were acceptable to the animal subjects and permitted the exercise of choice by them. Dr Richter's observations indicated how psychologic elements may operate in the choice of beverages.

It has been generally assumed that alcohol exerts a marked effect on the circulation because of the flushing and increased pulse rate it produces. Experimental studies as described by Dr Arthur Grollman, of Johns Hopkins University School of Medicine, showed that it actually exerts only a minor effect on the circulation, and that this does not reflect any significant change in cardiac activity. The isolated heart is not affected by concentrations that might be encountered in a human subject. Such changes as occur in the lower animals are to a large extent secondary to other changes in the organism. Alcohol causes an increased circulatory activity in the normal human subject, but the magnitude of response is so small

that a stimulant action on the circulation cannot be inferred. According to Dr. Grollman, the so-called "beer-drinker's heart" is probably due to the plethora induced by large volumes of malted fluids rather than to their alcoholic content. The ingestion of equal amounts of alcohol-free saline solution for the same period would probably induce a similar disorder. The apparent stimulating effect of alcohol in conditions involving circulatory insufficiency is probably due to reflex stimulation of the gastrointestinal tract.

Dr. M. Geneva Gray, of Harvard Medical School, discussed "The Effect of Stimulants of Cellular Oxidation on Alcohol Metabolism," especially the higher homologues of dinitrophenol. These compounds had been studied by Heymans, who suggested that they might be more active and less toxic than the latter substance in stimulating cellular metabolism. In Dr. Gray's experiments, the blood alcohol concentration of animals given a measured amount of ethyl alcohol by oral administration was determined at intervals during three-hour experiments, and the same procedure repeated about a week later, at which time one of the higher dinitrated phenols was administered in addition. Dinitrocyclohexylphenol, dinitrothymol, dinitro-orthocresol and sodium dinitro-orthocresol were found to increase the oxidation of alcohol in cats. They were also found to be effective in increasing the *in vitro* oxidation of alcohol in the presence of fresh liver and muscle tissue, but to a lesser degree. Because of the potential toxicity of these drugs, Dr. Gray stated, they cannot be recommended for use in human subjects, but the results suggest a pharmacologic approach to the treatment of acute alcoholism. It is possible that if the undesirable side actions could be eliminated or attenuated by synthetic technics, substances of this general type might be utilized in active therapy.

A paper on "The Metabolism of Alcohol" by Dr. Thorne Carpenter, of the Carnegie Institution of Washington, at Boston, was read by title. The need for clarification of many points regarding the metabolism of alcoholism was pointed out, and the previous work that had been done was shown in relation to the aspects of the subjects, which remain problematical.

The clinical aspects of alcoholism were the subject of the afternoon session on December 27. Dr. Philip Piker, of Cincinnati, read a paper entitled "The Symptoms of Alcoholism," in which he described the appearance and behavior of persons under the influence of varying amounts of alcohol. The attempted correlations between alcoholic symptoms and blood alcohol levels should be regarded with skepticism in the light of Dr.

Piker's findings with rabbits and human subjects.

Dr. H. Houston Merritt, of Harvard Medical School, spoke on "The Examination of the Alcoholic Patient," and described the many conditions that may be present coincidentally with alcoholic intoxication and serve to complicate the clinical picture. These include skull fracture, diabetic or uremic coma, various abnormal mental states and intoxications caused by other toxic agents. He emphasized the necessity of correct diagnosis in beginning appropriate treatment without delay. Dr. Merritt stated that examination of the cerebrospinal fluid can be particularly useful in the diagnosis of alcoholism.

"Chemical Tests in the Diagnosis of Acute Alcoholic Intoxication" was the contribution of Dr. Walter Jetter, of the Taunton State Hospital and the Department of Legal Medicine, Harvard Medical School. His paper comprised a critical survey of the available methods for the objective determination of alcohol in body fluids and tissues and described a new procedure devised by the author in which a sample of expired air forms the material for analysis. The results of psychologic tests, which had been correlated with chemical findings, were also presented.

The effect of chronic and acute alcoholism on the organs and tissues of the body, except for the liver, is not specific for alcohol. Changes that do occur are low grade, such as chronic irritation and mildly inflammatory processes possibly resulting in atrophy of the gastric mucosa, edema of the brain and irritation of the meninges, together with possible alterations in the kidneys. Cirrhosis of the liver is the only condition in which alcohol appears to play more than a minor part. These facts, pointed out by Dr. Arthur W. Wright, of Albany Medical College, suggest that the effect of alcohol, like that of other substances, is mainly physiologic and chemical rather than structural.

A new terminology was suggested by Dr. Norman Jolliffe, of Bellevue Hospital, New York City, for the diseases previously considered to be exclusively the result of alcoholism but now proved to be the effect of vitamin-deficient diets. Dr. Jolliffe suggested the terms "deficiency polyneuritis" instead of "alcoholic polyneuritis," "nicotinic acid deficiency encephalopathy" instead of "wet brain" and "pellagra" instead of "alcoholic pellagra" or "pseudopellagra." He pointed out that all deficiency diseases known to occur in man, such as scurvy, ariboflavinosis and vitamin A deficiency, also occur in alcoholic patients.

"The Causes of Death in Alcoholism" was the title of a paper by Dr. Timothy Leary, Medical Examiner of Boston. From his long and ex-

tensive experience, Dr. Leary reviewed a series of 1000 alcoholic deaths and pointed out that the alcoholic patient frequently dies from causes unrelated to alcohol itself. These include trauma, strangulation from unmastered food or vomitus, rupture of the cardia or hemorrhage resulting from vomiting, frost-bite gangrene, pneumonia and other conditions related to exposure and avitaminoses, particularly those with central-nervous-system manifestations. Only one third of the patients in the cases reported died of acute alcoholic intoxication. That alcoholism is a disease and as such can be prevented more readily than it can be cured was stressed in this paper and in the following one by Professor Anton J. Carlson, of the Department of Physiology, University of Chicago.

Dr. Carlson spoke on "The Alcohol Problem: Possible lines of useful research." He pointed out that a great deal of information is available regarding chronic alcoholism and temporary inebriety, and that the use of any amount of alcohol that impairs the personal, economic and social efficiency stands condemned. The realization that alcoholism is a contributory factor in producing crime and highway accidents and that it has an effect on longevity and on the germ plasm appears to be a more promising phase of research than extensions of previous studies on the effect of alcohol on the patient. The chief unknown factor in the problem remains the question why alcohol in a given amount will cause one person to become seriously intoxicated and will not affect another.

The morning session on December 28 was devoted to the neuropsychiatric features of alcoholism, and was opened by Dr. Foster Kennedy, of Cornell University Medical College, with a paper on the neurologic features encountered in chronic alcoholism. Dr. Kennedy reviewed the better-known syndromes and spoke with emphasis about alcoholic polyneuritis and cerebral conditions complicated by alcoholism. The clinical results of alcoholism in families were also discussed. Dr. Kennedy expressed the opinion that alcoholic indulgence was a factor that precipitated seizures in epileptic personalities and aggravated epilepsy when it was present in alcoholics. Dr. Kennedy's remarks were distinguished not only by their concise and scholarly quality but by the pleasing manner in which they were presented. His reference to the epidemic neuritis of 1903 at Manchester, England, was especially interesting.

Dr. Leo Alexander, of Harvard Medical School, presented a paper on "Neuropathological Findings in the Brain and Spinal Cord of Chronic Alcoholic Patients," illustrating it with many photo-

graphs of actual brain and cord specimens. Dr. Alexander stated:

The microscopic findings may be divided into two main groups: one group in which the neural parenchyma is damaged directly and primarily, best summarized under the term neuronitis, and the second group in which the neural parenchyma is affected only indirectly by means of primary damage to the vascular system, a syndrome which has been termed Wernicke's disease. . . .

Wernicke's disease can be defined pathologically as a syndrome characterized by small foci with degeneration, varicose deformity, and endothelial and adventitial proliferative change of vessels, and subacute necrosis of the parenchyma, which are found predominantly around the ventricular system. Small petechial hemorrhages may frequently (but not always) be present throughout the lesions. Wernicke himself named the disease "polioencephalitis hemorrhagica superior et inferior."

This disease has recently been reproduced in our laboratory in a series of animal experiments adapted to create a state of vitamin B₁ deficiency more severe than that which is sufficient to cause neuronitis. This experimental disease is topographically and histopathologically identical with Wernicke's disease in man. This disease is furthermore identical with a disease produced in foxes who have been allowed to over-indulge in raw fish.

We may, therefore, be justified to regard Wernicke's disease as caused by extreme depletion of vitamin B₁ or, more specifically in this instance, of thiamin chloride. This extreme depletion can be furthered by an over-abundant supply of other vitamins, particularly of riboflavin phosphate and of vitamins A and D. These and other combinations of over-dosage with deficiency have been used directly in our animal experiments. A similar situation is created by a raw fish diet, fish being rich in vitamins A and D and riboflavin, but deficient in vitamin B₁. In Japan, fishermen [who eat raw fish freely] are a group most outstandingly afflicted by beri-beri.

The majority of pathologic conditions encountered in the nervous system of chronic alcoholic patients is therefore attributable to associated vitamin deficiencies. These vitamin deficiencies are due to decreased intake by the alcoholic patient's choice or habit, decreased utilization by the diseased gastrointestinal tract, increased requirement by the increased caloric burden of metabolism, and possibly by a still unascertained specific destructive chemical effect of alcohol and fusel oils on ingested vitamins.

"The Effect of Alcohol on the Functions of the Nervous System" was described by Dr. Ross A. McFarland, of the Fatigue Laboratory, Harvard University. The psychologic findings on the mechanism of the action of alcohol bear out the theory that the main effect is cortical with an adventitious peripheral effect. Dr. McFarland pointed out that the most urgent need in psychologic experimentation is the exploration of individual tolerance to alcohol in contrast to acquired tolerance, which is termed "habitation." Such

a project can be carried out to the best advantage by the co-operation of physiologists and psychologists.

Dr. David Wechsler, of Bellevue Hospital, New York City, presented material on "The Effect of Alcohol on Mental Activity." Dr. Wechsler stated:

In appraising the effect of alcohol on mental activity, it is necessary to distinguish between transitory changes observed in acute alcoholic intoxication and the reputed permanent changes following chronic alcoholism. Observations regarding mental changes in the two conditions, while mutually supportive, are not interchangeable. Data regarding the effects of acute alcoholic intoxication are derived largely from circumscribed experimental studies with relatively few subjects, and concern themselves primarily with changes in mental psychomotor functions following the ingestion of variable doses of alcohol. Results of these studies reveal measurable loss in mental efficiency in most of the functions investigated.

Controlled studies on the mental effects of chronic alcoholism, though occasionally based on larger numbers, have usually been made under such variable conditions as to furnish data hardly more valid than those obtained through clinical observation. These studies confirm the loss in mental efficiency observed under experimental conditions and, in general, indicate a progressive, though uneven, deterioration in the global functioning ability and personality structure of the chronic alcoholic patient. Outstanding is the impairment of the subjects' ability to integrate, particularly at the higher functioning levels.

Dr. Wechsler's paper summarized these tendencies as revealed in available published data and as shown in his study of 40 patients with chronic alcoholism admitted to the Bellevue Psychiatric Hospital during the period 1938-1940. The value of the quantitative methods of clinical psychology was demonstrated, and the possibilities of further study by these procedures were discussed.

"Alcoholism and Mental Disease" was the subject of a paper by Dr. Nolan D. C. Lewis, of the Psychiatric Institute of New York, who differentiated between the various mental disorders due to, or acutely released by, overindulgence in and special sensitivity to alcohol. Dr. Lewis discussed the personality factors and characteristic reactions as they appear in such conditions as pathologic intoxication, delirium tremens, acute hallucinosis, paranoid developments and alcoholic deterioration. Some of these disturbances were, in Dr. Lewis's opinion, an expression of other psychoses. The role of alcohol in certain neurogenic conditions was discussed, and the relation of these disorders to other determining elements was brought into relief.

A paper by the late Dr. Paul Schilder on the "Psychogenesis of Alcoholism" was read by Dr. Merrill Moore. According to Dr. Schilder:

The chief effect of alcohol on psychologic function is that of reduced efficiency. There is a strong tendency toward impoverishment of associations and an egocentric form of behavior. The basic pattern of drinking varies with the situation of the individual and may be accompanied by an associated breakdown of sexual and aggressive impulses. Early childhood experiences may have required a variation in the pattern of sexuality which may appear during intoxication and may be characterized by violence. Acute alcoholic intoxication differs in the chronic alcoholic patient from that seen in an individual who is intoxicated for the first time. In the former, acute intoxication brings forward much primitive behavior with a corresponding increase in anxiety, the threat of which does not remain in the sphere of social insecurity but extends to sexual threats and even to the threat of castration and dismemberment. The chronic alcoholic patient has lived from earliest childhood in a state of insecurity, and alcohol appears to reverse this situation—at least during the period of its influence. The attitudes of parents toward children which will promote security and a normal amount of aggression and which will guarantee a reasonably free development of sexual adaptation will be powerful factors in the prevention of alcoholism.

Dr. Alexandra Adler, of Harvard Medical School, speaking on "The Individual Psychology of the Alcoholic Patient," stated:

Alcoholism, as well as many other neuroses, represents an escape from challenge and possible defeat. Alcoholic patients are usually unwilling or unable to assume responsibility, considering themselves victims of a mysterious addiction which they feel precludes the assumption of responsibility by them. The difference in the psychology of the chronic alcoholic patient and the dipsomaniac or periodic drinker appears to be quantitative. It is said that impotence is frequent in alcoholic patients and that this causes much of their psychopathology. The individual patient may claim abnormally strong sexual powers or he may be associated with homosexual circles. A jovial mood is typical of many chronic alcoholic patients, a fact which may amount to a minimizing of the importance of certain situations and thus form an escape from the need to assume responsibility. The psychotherapy of alcoholism is not greatly different from that of other neuroses but is more difficult and is complicated by the lack of reliability of the patient and the indifferences to responsibility, as well as a marked degree of shame over previous behavior.

Dr. E. Morton Jellinek, of New York City, speaking on "Heredity, Constitution and Alcoholism," reviewed some frequently quoted statistics on alcoholism, especially those offered as evidence of hereditary factors in relation to alcohol. His scholarly analysis and his critical comments were significant and instructive. Dr. Jellinek touched briefly on the work he had in progress. In concluding, he referred to the literature and summarized some current opinions concerning the hereditary aspects of alcoholism.

Mr. Lowell Trowbridge, of Boston, gave a pa-

per on "Alcohol Absorption and Behavior in Chronic Alcoholic Patients" This study was made in a state hospital on a group of male patients who were diagnosed as chronic alcoholics. Each drank 15 cc of alcohol per kilogram of body weight in a grapefruit juice solution. The first hour following the ingestion of alcohol, and hourly for four hours thereafter, venous bloods were determined and overt behavior of the subjects was measured by psychologic tests. A fifth and final observation on behavior was made, and a final sample of blood was taken at the sixth hour. When the entire group was considered, there was some correlation between performance and blood alcohol concentration, but this was not apparent when individual members of the group were studied.

Dr William G Lennox, of Harvard Medical School, discussed "The Influence of Alcohol on Convulsions in Epilepsy." Dr Lennox reported a statistical study of the records of 1254 patients with epilepsy who were over fifteen years of age. Of these, 26 per cent used alcohol moderately, and 6 per cent used it to excess, these figures are not greater than those for a control group. Alcohol was used less by women than by men, and to the same extent by essential and symptomatic patients. There was a progressive increase among older patients. This increase was proportionately greater among men than among women. The number in whom alcohol was observed to be a factor in producing seizures was 6 per cent of all patients and 21 per cent of those who used alcohol. The proportion was greater among men than women, and among symptomatic than among essential patients. The proportion of seizures after the use of alcohol was less among older patients, and was much greater in patients who used alcohol frequently than in those who used it infrequently. In the group of frequent users 57 per cent reported that seizures sometimes or often followed indulgence. Dr Lennox concluded:

The physiologic or chemical mechanism by which this narcotic drug produces seizures in predisposed persons in the sobering up period is not clear. Various means of solving interrelated problems of alcoholism and of epilepsy are suggested. The need for an electroencephalographic survey of alcoholic patients and their relatives is particularly urgent.

On the afternoon of December 28, the treatment and prevention of alcoholism were discussed. Dr Wilfred Bloomberg, of the Boston City Hospital, discussed the medical treatment of alcoholism, with special reference to the use of benzedrine sulfate, emphasizing the toxic action of alcohol itself. The elimination of alcohol and dehydra-

tion were considered, together with sedation of various types. Dr Bloomberg presented a statistical report of results in 60 cases in which benzedrine sulfate was used as an aid to the treatment of the chronic phases of alcoholism.

"Treatment of the Alcoholic Addict" was the subject of a paper by Dr Robert V Seliger, of Johns Hopkins Hospital, who presented a discussion of hospital, farm and extramural treatment and the selection of the type of treatment, partly on the basis of the patient and his condition and partly on the basis of his life situations at the time. The importance of careful investigation of all medical, psychologic, psychiatric, social and behavior aspects and of all available facts of the case was emphasized by Dr Seliger. The methods and procedures followed in each type of treatment were described in detail.

Dr Karl M Bowman, professor of psychiatry, New York University College of Medicine, and director of the Division of Psychiatry, Bellevue Hospital, reviewed the literature on the treatment of delirium tremens. The opinions of different authorities on the subject were critically evaluated. Dr Bowman finally suggested a method for treatment based on the limitation of restraint to a minimum, the use of paraldehyde as a sedative, the combating of dehydration and acidosis by forcing fluids and giving malt, the use of a high-calorie diet in addition to insulin, and the use of vitamins—particularly the vitamin B complex.

The late Dr Charles E Parsons, of the Washingtonian Hospital, Boston, said in discussing "The Problems and Methods in a Hospital for Alcoholic Patients"

There were 195 convictions for drunkenness per 10 000 population in Boston for the year 1938-1939 as compared with 1131 for the same period for England, Scotland and Wales. Fifty-two per cent of the deaths from poisoning for the ten year period of 1928-1937 for Massachusetts were due to alcohol. The Washingtonian Hospital in Boston tries to do its share in meeting these problems. It cared for 454 cases between March 1, 1940 and December 1, 1940, and the mortality rate for all cases was 0.65 per cent. Because nine tenths of patients cared for are working and families are dependent on the income from the jobs, hospitalization has been limited by social and economic pressure to an average of eight days. Further care is supplemented by evening outpatient recall visits and by working parole—where the patient lives in the hospital but goes to work and returns there. This prolongs the period of protection and psychotherapy. The chief immediate problems on admission are the care of the acute alcoholic intoxication and the handling of vitamin deficiency when present. A later problem is working out psychologic and environmental adjustments.

The private psychiatric hospital was viewed by Dr. Henry M. Tiebout, physician-in-charge, Blythwood, Greenwich, Connecticut, as an important way station on the road to health. Beyond its opportunity for rehabilitating the body of the individual alcoholic patient, it has a specific job: starting the patient to think and figure straight about his problem. The paper centered about a discussion of how to effect this start toward a normal pattern of life.

Dr. Bernard Glueck, of Stony Lodge Foundation, Ossining, New York, criticized the present-day methods of treating alcoholism. He had found that the difficulties in treating the problem drinker were the resistances from patients who did not want to be cured, the commonly encountered ambivalent attitude toward treatment on the part of relatives, the absence of anxiety, discomfort and sometimes acute suffering, which in the psychoneurotic patient are the most potent motives for continuance of treatment, and the moral and esthetic prejudices that still cling to alcoholism. In view of these difficulties, it is not surprising that treatment often fails. However, as Dr. Glueck pointed out, these causes are manageable for the most part, and are not due to the inherent psychodynamics of the drinker.

Dr. Charles H. Durfee, of Rocky Meadows Farm, Wakefield, Rhode Island, undertook to correct some popular misconceptions, held by physicians and laymen alike, concerning alcoholic patients and alcoholism. He cited seven of the commoner beliefs, and then proceeded to show, from his experience in the study and treatment of alcoholic patients, the fallacies and erroneous assumptions on which these beliefs rest.

For example, contrary to the widespread notion that the use or abuse of alcohol can be controlled by will-power, Dr. Durfee maintained that will-power has relatively little to do with the problem of drinking, and that the habitual drinker cannot stop drinking merely by making up his mind not to drink. By concentrating on abstinence he is inducing a state of mind that, because of his preoccupation with the problem, is self-defeating. He is still "thinking alcohol," that is, dealing with the symptom instead of the cause, trying to think his way out of his problem instead of acting his way out. Alcohol cannot be fought: it must be circumvented, according to Dr. Durfee. The indirect approach is better than a head-on struggle with the alcoholic habit.

Dr. Durfee held that there is no alcoholic type. There are only people who drink for various reasons. Many are in need of psychiatric care. Others, whom he designated "problem-drinkers," need psychologic re-education; a few, merely re-

direction and reorientation. Similarly, there is no such thing as a physiologic craving for alcohol, he stated. The craving is fundamentally psychologic, expressed in the need for relief from tension. Once the drinker is relaxed and able to eat and sleep again, his need for alcohol may diminish.

Other misapprehensions dealt with included the fact that a person with a long alcoholic history is more difficult to rehabilitate than a young person, that the lone drinker is far more difficult to help than the social drinker, and that alcohol must be rigidly kept from the patient while he is under treatment.

Dr. Durfee also took issue with some of the so-called "cures" for alcoholism and exposed the erroneous and often spurious conceptions and claims underlying these cures. A genuine cure does not mean mere abstinence over shorter or longer periods of time, but results in or follows a radical personality readjustment that does away with the need for alcohol.

The morning session on December 29 covered the social and legal problems of alcoholism. Dr. Lawrence Kolb, of the United States Public Health Service, stated in a paper on "Alcoholism and Public Health":

Alcoholism is a serious health problem that has been handled largely by police authorities, with the result that the alcoholic patient has been treated as a criminal rather than as a sick individual. Present-day methods of handling chronic alcoholic patients are ineffective or harmful. An intensive study of the prevalence and causes of alcoholism and effects of alcohol are necessary in order to establish a sound basis for better methods of prevention and cure.

"Some Statistical Facts about Alcoholism in Massachusetts" by Dr. Neil C. Dayton, of the Massachusetts Department of Mental Health, revealed that the records of one fifth of all admissions to mental hospitals in Massachusetts between 1917 and 1933 indicate that chronic alcoholism was a prominent etiologic factor. Of 56,579 first admissions in this period, 32 per cent of the male patients were classified as intemperate in the use of alcohol, and 33 per cent in addition were found to have used alcohol to some extent. The female patients among the first admissions used alcohol much less. Chronic alcoholism was highest among these patients in 1917 and lowest in 1920. The latter year was also the lowest in total admissions to mental hospitals. Both sexes showed the highest percentage of chronic alcoholism between the ages of thirty and sixty years. The incidence of alcoholism among mental patients generally bore an inverse ratio to the educational level and the economic status. Unmarried pa-

uents showed a lower incidence of alcoholism than married, widowed or divorced persons in the group studied. The urban centers were high in alcoholism, and the rural areas were low. Foreign born persons were high in intemperance, but a change in trend seemed to have occurred within a few generations. These data were derived as part of a study made in Massachusetts state mental hospitals, sponsored by the Laura E. Spelman Rockefeller Foundation.

The major problems concern the meaning of "drunkenness" and "under the influence of liquor," the methods of proving these states exist, and the differentiation of drunkenness in relation to various other circumstances of public importance, as well as the improvement of treatment through standards based on sociologic and psychiatric knowledge, comprised the subject matter of an address by Dr. Jerome Hall, professor of law, Indiana University Law School. Dr. Hall stressed the need for uniform legislation.

Professor Edwin R. Keedy, of the University of Pennsylvania Law School, spoke of the legal responsibility of the alcoholic patient, and described the many situations in which this becomes a vital question. The relation of alcoholism to highway safety and to crimes of violence is among the commoner aspects of the legal implications of alcoholism.

Mr. Morris Ploscowe, clerk of the Court of Special Sessions, New York City, drew on his long experience with those addicted to alcohol to describe the method by which New York City handles the many persons who are arrested for drunkenness. Mr. Ploscowe admitted that these prisoners were inadequately handled, and he made a number of recommendations about their future treatment by the courts.

"The Penal and Correctional Aspects of the Alcoholic Problem," a paper by Austin H. McCormick, executive director of the Osborne Association, pointed out the need for the establishment of colonies of the farm, forest or work camp type for inebriates. Mr. McCormick stated that the frequent failure of the splendid facilities for the treatment of alcoholism at Riker's Island in New York is due to the poor physical condition of the persons sent there, and to the short sentences imposed in an effort to reduce the prison population of the city. He considers at least one year, preferably a longer period, necessary to initiate rehabilitation. A substantial progress has been made in state and federal prisons, and an enlightened viewpoint prevails in many of them, where progressive officials talk of care and treatment instead of custody and punishment. How-

ever, this is not true of some county jails and local institutions.

The final session for the presentation of original papers was held on the afternoon of December 29, when the discussion of the social and legal problems of alcoholism was concluded. Dr. Horatio M. Pollock, of the New York Department of Mental Hygiene, discussed the social costs of alcoholism, reviewing available facts concerning the present day use of alcoholic beverages in the United States, and discussing the effect of such use on economic status, employment, crime, physical illness and mental disease. Some suggestions were offered relating to ways and means of lessening the unfavorable effects of alcohol.

Mrs. Harriet R. Mowrer, of Evanston, Illinois, spoke on "Alcoholism and the Family." Mrs. Mowrer stated:

Alcoholism is one of the many problems of personality adjustment which have their genesis in the complex of familial relationships out of which the patterns of personality are developed. The cultural background and economic adjustment are important in measuring the individual response to family organization. The alcoholic individual is characterized by shifting occupation, restlessness and lack of definite drive. There is a strong association between alcoholism and sexual factors. Marital discord is not the result of alcoholism but the result of the same etiologic factors. The alcoholic individual tends to enter marriage handicapped by some economic insecurity, dissatisfaction with occupational choice and a tendency to resort to substitute adjustment devices. The personality disorganization of the alcoholic patient can only be understood as it performs a function in the attempt at social adjustment by the individual.

"Alcohol is a Factor in Traffic Accidents" was discussed by Dr. Donald S. Berry, secretary, Committee on Tests for Intoxication, National Safety Council. He stated that about one third of all fatal traffic accidents involve a driver or a pedestrian under the influence of alcohol. The police have trouble in convicting obviously guilty drivers because the observed conditions may have been claimed to be due to illness, injury or medication. Chemical tests eliminate guesswork and have been used successfully in at least twenty-seven states. Dr. Berry recommended that they be more widely adopted.

Dr. Jeremiah P. Shalloo, of the University of Pennsylvania, speaking of the cultural factors involved in alcoholism, said:

It is culturally imperative to toast the bride, christen the ship, seal the bargain, speed the friend, salute the New Year, celebrate good fortune, wake the dead and even symbolize and ingest the blood of the Saviour through the medium of alcohol. With so many various forms of culturally approved drinking, the

amazing result is that we have so few persons emotionally dependent on alcohol in some form. The teetotaler is, after all, equally as abnormal from the cultural standpoint as is the habitual drinker. . . . Social habits which develop in response to cultural sanctions cannot be eliminated by sumptuary legislation.

Dr. Shalloo declared that the failure of prohibition was eloquent testimony of the essentially alcoholic nature of contemporary American culture. In conclusion, he pointed out the relation of the cultural background of an alcoholic individual to the form that his addiction may assume. That alcohol has been used throughout the ages does not lessen the need for the control and prevention of alcoholism in the twentieth century, he stated.

Dr. George S. Stevenson, of the National Committee for Mental Hygiene, gave the closing paper at this session. His subject was "Education and the Control of Alcoholism." Dr. Stevenson stressed the need of mental hygiene in colleges and educational institutions, "where alcoholism often begins." He spoke of the advantages that could be utilized generally by the dissemination and application of information such as a fact-finding organization might develop. In conclusion, Dr. Stevenson emphasized the value of preventive measures that might be applied to alcoholism.

After these papers had been read, discussion from the floor was invited. Among suggestions made was one from Dr. Leo Alexander, of Boston, which was indorsed by Drs. Merrill Moore and Abraham Myerson, of Boston, namely, that a great deal of the damage caused by alcoholism might be prevented if the provisions of the Food, Drug and Cosmetic Act of 1938 were applied to the advertising and sale of alcoholic beverages. Dr. Alexander stated:

Alcohol is both a food and a drug under the definitions of this act. The food section of this act intends . . . to protect the public from the sale of imitations under the name of the original product. If this provision were applied to alcoholic beverages, many of the so-called blended whiskeys would have to be sold under their correct name which is "imitation whiskey" or "freshly distilled grain alcohol with whiskey flavoring." There is no doubt that properly aged whiskeys are less injurious to health than freshly distilled grain alcohol. The act considers any food misbranded which is offered for sale in the name of another food or which is an imitation of another food, unless its label bears in type of uniform size and prominence the word "imitation," and, immediately thereafter, the name of the food imitated. The drug section of the act states that a drug is misbranded unless its label "bears adequate directions for use and such adequate warnings against use in those pathological conditions or by children, where its use may be dangerous to health, or

against unsafe dosage or methods or duration of administration or application, in such manner and form, as are necessary for the protection of users."

The following label, in conformity with the Food, Drug and Cosmetic Act of 1938, was proposed by Drs. Alexander, Moore and Myerson:

DIRECTIONS FOR USE: Use moderately and not on successive days. Eat well while drinking and, if necessary, supplement food by vitamin tablets while drinking. WARNING: May be habit-forming; not for use by children. If this beverage is indulged in immoderately, it may cause intoxication (drunkenness); later, neuralgia and paralysis (neuritis) and serious mental derangement, such as delirium tremens and other curable and incurable mental diseases, as well as kidney and liver damage.

Surgeon-General Thomas Parran, of the United States Public Health Service, presided at the final meeting, held during the evening of December 29, which was open to the public. He discussed the attitude of the federal government toward major health problems, and observed that it was not inconceivable that alcoholism might soon take its place beside those other disease conditions once thought uncontrollable but now better understood, such as tuberculosis, syphilis and cancer. Dr. Parran introduced Dr. Abraham Myerson, director of psychiatric research, Boston State Hospital, who made the principal address of the meeting. Dr. Myerson's subject was "The Social Pharmacology of Alcoholism." He stated that there is some danger that overemphasis may be laid in two directions in considering alcoholism. In the first place, the role of the vitamins should not obscure the fact that alcohol is in itself a narcotic drug and that it very probably has chronic effects that are independent of the role of the vitamins or, if not independent, of primary intrinsic importance. This also brings to light the fact that certain drugs have a useful role in the treatment of acute and chronic alcoholism, especially amphetamine sulfate, Metrazol and the combination of insulin and glucose.

The second overemphasis may be placed on the neurosis of the alcoholic patient. It is perfectly true that the person who becomes chronically addicted does so in response to social and emotional difficulty. Yet there are people in the population who do not become alcoholic, who have plenty of social and emotional difficulty, and who have a high incidence of other neuroses and psychoses. Dr. Myerson concluded:

It must be taken into account that the social attitude toward the drinking of alcohol is one of the most

important things in our civilization. Thus, alcohol is the drug used to enhance good fellowship and to evince gaiety and celebration as well as ceremony. In other words, to class it simply as a drug of escape or for the purpose of bringing about oblivion is only expressing one phase of its psychologic use. The other phase—celebration and ceremony—is of great value for us to understand. Moreover, the measure of personality worth has, to a certain extent and in large

segments of the population, become the ability to handle alcohol—in other words, to be able to drink large quantities. The whole attitude of society toward the use of alcohol and toward the alcoholic patient has become decidedly ambivalent. This total social pressure must be met by social means, social re education and social legislation, as perhaps the most important parts of the prevention of alcoholism.

MEDICAL PROGRESS

THE ADRENAL CORTEX IN HEALTH AND DISEASE

JOSEPH C. AUB, M.D.*

BOSTON

PHYSIOLOGIC AND CLINICAL EFFECTS

THE adrenal cortex, essential for life, has a large factor of safety. Only when it is largely depleted do signs of Addison's disease develop. Two chief manifestations of its functions then appear. First, a lavish excretion of urinary sodium chloride and water occurs, with a resulting reduction of the sodium chloride and water content as well as volume, of the blood plasma. There often appears a concomitant rise in plasma potassium. This effect on body electrolytes is the best known of the adrenocortical functions. Secondly, there is a tendency to hypoglycemia because of a close relation to carbohydrate metabolism.

But there are also obvious effects on the fatigue of muscles, on growth and sex and on resistance to various strains and stresses, such as infections or temperature changes. There is also a fall in the basal metabolic rate. The relation to pigment metabolism, with the striking discoloration that occurs in Addison's disease, is evident but not understood.

It is not too clear how the adrenal cortex accomplishes its control of plasma inorganic salt levels, but the work of Harrison and Darrow¹ implies that the kidney is at least one of the primary factors. These workers found that the normal kidney functions of tubular reabsorption of sodium when the blood sodium is low, and the increased excretion of potassium when the blood potassium is elevated are lost in dogs with adrenal insufficiency. In the latter deficiency, the decrease in plasma sodium does not arrest sodium excretion, and even though the blood volume has diminished, the urine volume remains elevated and its sodium content remains high. But though the blood plasma potassium rises under these conditions, it is only sluggishly excreted by the adrenal

deficient kidney. If sodium chloride is given to an animal with such an insufficiency, it produces a diuresis that sweeps out the sodium and some retained potassium as well, but the capacity to store sodium and to excrete a high concentration of potassium is restored only by treatment with cortical extract. This work was confirmed by Anderson et al.²⁻⁵ by means of radioactive salts; they found that animals could be kept practically normal if 1 per cent sodium chloride was added to their drinking water. They remained normal not only in their sodium and potassium levels but also in their ability to gain weight and to store glucose. It therefore appears that the inorganic disturbance produced by adrenal insufficiency bears some relation to the second function of the cortex—namely, carbohydrate metabolism.

The relation of the adrenal cortex to carbohydrate metabolism and its antagonism to insulin have been repeatedly investigated in the past by Britton and Silvette, Long and Lukens, and many others. There is still some disagreement about this relation, for Grollman⁶ thinks that the adrenal gland is not preeminently involved in the maintenance of normal carbohydrate metabolism. According to such investigators, the abnormalities observed represent only the poor condition of the adrenal-insufficient animal and not a function of the gland itself. On the contrary, other recent investigators again find a close fundamental relation between the adrenal glands and the carbohydrates. This viewpoint was primarily advanced by Britton and Silvette,⁷⁻⁹ Kitzin and Long⁹ described the effect of cortical extract as increasing the glycogen in the liver without affecting muscle glycogen. This observation has been confirmed by Sprague,¹⁰ who showed that the phenomenon occurred in both fasting normal and depauperized rats. The work has been strikingly summarized by Long, Kitzin and Fry,¹¹ who appear

*Associate professor of medicine, Harvard Medical School, physician in chief, Coll. P. Huntington Memorial Hospital.

to demonstrate clearly the fundamental importance of this adrenal function. The cortical hormone, corticosterone, apparently decreases the proportion of glucose oxidized and increases its deposition. In depancreatized rats, adrenalectomy decreases and corticosterone increases glycosuria above the previous levels. This hormone raises the blood sugar of hypophysectomized rats even to "super-normal levels."

Thorn and his co-workers¹² have recently reported that "the ability of adrenalectomized animals to convert three carbon atom intermediate substances of carbohydrate and protein metabolism to glucose or glycogen is markedly impaired." They also noted an increased utilization of glucose by the adrenalectomized animal. These factors—poor formation but rapid use of glucose—account for the rapid exhaustion of the glycogen stores in fasting animals.

With these effects on carbohydrate metabolism Long and his associates¹¹ have also demonstrated an effect on protein metabolism, inasmuch as the cortical hormone stimulates nitrogen excretion. They suggest that increased gluconeogenesis from protein destruction may explain the elevated carbohydrate levels and the increased nitrogen and potassium excretions that result from the use of cortical extract in animals.

The loss of adrenal cortex thus appears to diminish the production of carbohydrate from protein breakdown, whereas the use of Kendall's Compound E or corticosterone produces a return to normal conditions. These were also the findings of Wells.¹³

An interesting clinical confirmation of this work is found in a diabetic patient who developed Addison's disease. Bloomfield¹⁴ reported that as Addison's disease developed the need for insulin fell markedly, and the use of desoxycorticosterone produced no obvious effect on carbohydrate metabolism; cortical extract was followed by a return of higher blood-sugar levels.

The most dramatic recent evidence for the importance of the adrenal gland to carbohydrate metabolism is the observation by Cope and his co-workers¹⁵ that in adrenocortical insufficiency in the dog there is a very marked rise in serum-amylase activity. They find that this change in activity is the most sensitive objective measurement in the blood of cortically insufficient dogs, for it becomes significantly elevated before any change in electrolyte substances can be observed. They also note that both adrenocortical extract and desoxycorticosterone acetate depress this elevated level. This is a very interesting early effect on circulatory enzymes that have to do with carbo-

hydrate catabolism, and it is surprising that the effect should be so prompt. The observation should be investigated in clinical cases of Addison's disease.

Many of these experimental abnormalities of carbohydrate metabolism can also be found in clinical cases with Addison's disease, as Thorn and his co-workers¹⁶ have well summarized. They discovered that a large proportion of patients showed striking hypoglycemia following glucose-tolerance tests or after various stresses like fever or fasting. There was a decreased threshold at which hypoglycemic symptoms appeared, and also little tendency to an elevated blood sugar with either the ingestion of glucose or the injection of adrenalin. These workers confirmed the specificity of certain adrenal compounds to correct these abnormalities, of which adrenocortical extract was most effective, though Compound E of Kendall and corticosterone were also satisfactory. An interesting finding was the persistence of carbohydrate abnormalities in patients by means of desoxycorticosterone acetate therapy, in spite of a return to normal in electrolyte balance, plasma volume and blood pressure. This is confirmed by Wilder,¹⁷ who found a persistent low blood-sugar level and a continued inability to withstand short periods of fasting.

The relation of the adrenal cortex to muscular fatigue has been studied in animals by Secker,¹⁸ who found that adrenalectomy was followed promptly by well-marked fatigue, which was relieved within a few minutes by the injection of adrenocortical extract. As Thomson and Collip¹⁹ point out, the surprising thing is the speed with which these changes occur.

McGavack²⁰ was intrigued by the small size of the heart in Addison's disease, a finding that has previously been noted at autopsy. He studied the reduction in heart volume and found this to be 32 per cent in 5 cases of Addison's crisis, and 16 per cent in 3 cases without crises. It was only during crises that he observed a significant reduction in blood volume, which plays an accessory role in further reducing the size of the heart. Two patients who were studied after adequate treatment demonstrated a return to a normal heart volume.

The relation of the adrenal cortex to sex development is clearly seen in the tumors of man. Adrenocortical hyperplasia or neoplasia produces precocious puberty in childhood, particularly toward the masculine sex, and causes a similar appearance of sex reversal in adult women. As described by Aub and Nathanson²¹ these changes are analogous to the effects of testosterone inasmuch as they affect the secondary sex character-

istics, such as the penis and clitoris, but do not influence the primary gonads, such as the testes. Gross²² has also described these patients. It is not surprising that such changes might occur because of the production of androgens in the adrenal gland. In a recent publication, Wolfe, Fieser and Friedgood²³ describe the isolation of several androgens from the urine of a girl with a malignant adrenal tumor. They isolated five ketosteroids in which the androgen-breakdown product, dehydroisoandrosterone, represented about a hundredfold increase above normal. Others²⁴ have likewise found excessive amounts of male hormones in the urine of adrenal virilism cases. The independent diagnostic value of determinations of urinary 17-ketosteroid excretion is limited to such cases.²⁵ Furthermore, several of the female sex hormones have been isolated from adrenal glands (such as estrone and progesterone) by Beall and Reichstein.²⁶⁻²⁸ Indeed, Callow, Callow and Emmens²⁵ conclude that 17-ketosteroids and androgens may be derived from both the gonads and the adrenal cortex, and suggest the hypothesis that absence of the gonads leads to compensatory activity of the adrenal cortex in their production.

A good summary of the clinical literature in regard to the sex factors of the adrenal gland has been made recently by Looney²⁹ and therefore does not need to be repeated. He concludes that "the weight of evidence at the present time indicates that the life-sustaining principle does not of itself affect the gonads, that certain cortical extracts have a marked effect on the sexual development of experimental animals, and that, therefore, there are present in the adrenal gland substances distinct from cortin which have gonadic activity."

There is one interesting and neglected fact about these cases of overactive adrenal glands, particularly in children. The effect may be a reversal of sex characteristics, as in girls and occasionally in men.³⁰ But in boys the effect is simply an early maturation of all secondary sex characteristics — the metamorphosis occurs quickly, but once it has been accomplished, no further progressive changes in the stimulated organs occur. In other words, the overactive adrenal gland is simply a maturing factor.

It must also be remembered that Cushing's syndrome may well be due to hyperfunction of the adrenal cortex. This large subject cannot be adequately handled here, but it has recently been well reviewed by Haymaker and Anderson.³¹

BIOCHEMISTRY

Chemical knowledge of the adrenal cortex has developed rapidly since the discovery, and syn-

thesis by Reichstein,³² of one of the active principles, corticosterone. Koch³³ has recently summarized the literature.

There are at least four well-known compounds (corticosterone, 11-dehydrocorticosterone, desoxycorticosterone and C, 17-hydroxydehydrocorticosterone); the last is Compound F of Wintersteiner and Pfaffner or Compound E of Kendall. An ester of desoxycorticosterone is the common form of synthetic compound now on the market. The cortical extract obtained from the adrenal glands probably contains a mixture of many such compounds.

Mason³⁴ states that more than twenty closely related crystalline substances have been isolated from the gland, and still "the major portion of the total activity of the crude extract remains in the mother liquors from which the crystalline fractions have been removed." This impure residue is fifteen times as potent as desoxycorticosterone and one hundred times that of corticosterone. The isolated substances are all four-ringed compounds of the group called steroids (like sterol), and are closely related chemically to all the sex hormones. In fact, it is highly likely that estrogens, androgens and progesterone are synthesized in the adrenal glands as well as in the sex glands.

It is very interesting that compounds so closely related chemically should have such divergent effects. In some compounds a mixture of effects may be seen. Thus Mason³⁴ states that desoxycorticosterone acetate has progestational activity. The marked changes in growth and function and in body configuration produced by the sex hormones, compared with the metabolic effects of the very closely related adrenal steroids, give as dramatic a picture of the effects of very small chemical changes as can be found. The only difference between desoxycorticosterone and testosterone is that the former has a short ester chain replacing an oxygen atom, — yet it influences salt metabolism to a degree that represents health or death and has no androgenic effect, — whereas testosterone shortens the duration of the life of an adrenalectomized animal, but produces the changes in the body commonly ascribed to maleness. No chapter in chemistry is more interesting than this recent development.

The various isolated compounds, although closely related, have different therapeutic effects on the adrenal-insufficient organism. Thus some are not active, whereas desoxycorticosterone, which has few oxygen atoms, is the most effective compound in combating the sodium chloride loss produced by deficiency. It has, however, but feeble effect in correcting the carbohydrate abnormality of

metabolism.¹⁶ On the contrary, the closely related Compound E of Kendall apparently has an effect on the carbohydrate metabolism and on the fatigue phenomenon of muscle and a very weak salt-correcting quality, and corticosterone has some effect on both elements of metabolism.²¹

This great difference in effect may well account for the better responses sometimes produced by an extract of the adrenal gland rather than the therapeutic effects produced by single synthetic compounds. The impure extract isolated from the gland tissue represents a mixture of the compounds that are sometimes needed in therapy. This problem of the specificity of effects is well summarized by Kendall,³⁵ who has done much work in this field.

The administration of adrenal extracts may produce atrophy of the adrenal glands. Wells and Kendall³⁶ report that this is produced by corticosterone and Compound E, but not by desoxycorticosterone acetate. This is fortunate, for the compound most widely used in therapy is therefore least deleterious to the remaining adrenal tissue. It is interesting that Clausen³⁷ has recently reported that a similar atrophy may follow injections of progesterone.

Synthetic hormones do not produce such a refractory state with repeated injections as may develop from extracts of the adrenal glands. Hartman's³⁸ evidence indicates that refractoriness to the sodium factor in cortical extracts is due to an immunity that develops in adrenalectomized animals as easily as in normal animals. The pseudoglobulin fraction of the blood serum is responsible for the refractory state, which does not develop from extracts made from the same species as the subject. Because of this phenomenon Hartman advises against intravenous use of cortical extracts.

TREATMENT OF ADRENAL DEFICIENCIES

The treatment of Addison's disease has been well summarized by Loeb and his associates³⁹ and also by Thorn.^{40, 41} The specific treatment consists in using the most effective of the synthetic adrenocortical hormones, desoxycorticosterone acetate. This is not a perfect form of therapy, for it controls the salt loss but does not influence the abnormal carbohydrate metabolism of the disease. It would be better in the present state of knowledge to use the corticosteroids derived from the adrenal glands themselves, for this would give a more balanced mixture of the group of elaborated chemicals. But the use of such glandular extracts lacks uniformity of effect, and is very expensive. Its lack of dependability and the immunity that

may follow its use are, of course, serious matters in a disease in which crises may be of grave prognosis.

Desoxycorticosterone acetate can be used in three ways: First, by mouth, when very large quantities of this expensive drug are required. This method is also not desirable when gastrointestinal upsets are present, for absorption rates may be depressed at just the time when the therapy is most needed. The successful therapeutic use of desoxycorticosterone acetate, by applying it under the tongue, has been described by Anderson, Haymaker and Henderson⁴²; when the drug was dissolved in propylene glycol, the absorption appeared adequate and as effective as when it was given in oil intramuscularly. The usual method of administration is the intramuscular use in oil. This is usually a very satisfactory technic requiring at least several injections a week but with a fairly steady absorption rate. Finally, insertion as a solid pellet subcutaneously, an ingenious technic developed by Thorn,⁴⁰ has several advantages inasmuch as pellets have to be inserted only every few months, the absorption rate appears constant, and the amount of compound needed is relatively low. Once the diagnosis is clear and the constant need for the drug established, this appears the treatment of choice.

It is clear that desoxycorticosterone acetate should be first given intramuscularly in oil to establish whether it produces beneficial effects and how much is needed. Thorn recommends giving 6 to 8 gm. of added sodium chloride a day by mouth, and daily injections of 2 to 5 mg. of the drug. The patient ought to gain weight at once, for there should be a storage of sodium, chloride and water in the extracellular fluids. But a gain of more than a pound a day during the first week or a half pound subsequently means that too much of the hormone or too much salt is being given.

Wilder¹⁷ recently discussed the treatment of Addison's disease in a large number of patients at the Mayo Clinic. A low-potassium diet—a previous scientific contribution of the clinic⁴³—appeared to improve the clinical condition of the patients. The introduction of desoxycorticosterone acetate,⁴⁴ however, further improved the therapeutic results, although investigation soon revealed hypertensive blood pressures, increased venous pressure, peripheral edema and deaths from acute heart failure. Restricting the amount of salt added to the diet and discontinuing the reduction of potassium have appeared to remedy this problem in therapy. It is, of course, clear that an excess of desoxycorticosterone must not be given, for it may produce such an increased blood volume as to elevate the venous

pressure considerably. This may account for the cardiac failures. It is possible that the low-potassium diets accentuate this.⁴⁵

McGavack⁴⁶ stresses further the serious cardiac damage in Addison's disease that may follow an excessive intake of salt or adrenocortical hormone, as well as a marked reduction of potassium intake. Overtreatment, which may result in cardiac-muscle weakness, anasarca and hypertension, can easily be avoided now that it is recognized. McGavack also suggests that an ample intake of vitamin B may prevent the appearance of cardiac failure.

The treatment of the crises not infrequently seen in Addison's disease requires particular care. Not only is the synthetic drug, desoxycorticosterone acetate, badly needed in doses of about 25 to 35 mg., but the use of the aqueous gland extract is also desirable. But to these must be added warmth and careful intravenous therapy with saline and glucose solutions. A normal blood-sugar level must be maintained, as well as an elevated blood-sodium level. This phase of treatment is well described in the article by Thorn and Fitor.⁴⁰

Once the crisis is over and daily maintenance doses are established, the problem of pellet implantation should be considered. Thorn recommends "one pellet of from 100 to 150 mg being used for each 0.4 to 0.5 mg. of the material necessary for maintenance."

OTHER USES FOR CORTICAL HORMONES

Lindsay and his co-workers⁴⁷ urged the use of desoxycorticosterone as treatment for the Waterhouse-Friderichsen syndrome, the bilateral adrenal apoplexy of childhood. When such a diagnosis can be made, this therapy certainly deserves a thorough trial.

Perla and Marmorston⁴⁸ suggest that cortical hormone, with adequate salt and water in the diet, is of value in "maintaining patients with severe infections," such as pneumonia.

The analogy between adrenal insufficiency and traumatic shock was first suggested by Swingle et al.⁴⁹ The idea was not generally accepted, but recently has received more attention; several investigators have tried with some success the use of cortical extract, or desoxycorticosterone, in preventing or combating traumatic shock.⁵⁰⁻⁵¹ This is an interesting idea, which might be of particular importance in these days of war. There is a possibility that the hormone might produce salt storage in the body, and a little evidence that this would stay in the circulation, from Ragan, Ferrebee and Fish⁵⁰ Selye, and Dosne et al.^{61, 62} believe that cortical extract is better than desoxycorticosterone acetate, and Swingle and his associates^{55, 56}

imply that the action suggests a direct effect on the tonus of the peripheral circulation rather than on the electrolytes or carbohydrate metabolism. Most of these studies deal with the prevention of shock rather than its cure, and further investigations are needed before this work can be considered worthy of use in clinical cases.

* * *

The last few years, therefore, have seen a transformation in the conception of the adrenal gland. Its functions are fairly well understood, its active secretions not only isolated but capable of synthesis in the laboratory, and its treatment improved to a point where many patients can return from invalidism to prolonged active life.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27201

PRESENTATION OF CASE

A sixty-two year-old man entered the hospital for study.

Because of the patient's condition the history was obtained from his physician's letter and the nurse's report. It appeared that the patient had been well until two months before admission, when he complained of "fuzziness in the head" and inability to concentrate. One month before entry, a short period of aphasia developed, but neurologic examination was otherwise negative and the blood pressure was 144 systolic, 96 diastolic. He remained in bed for three weeks, but failed to regain his strength, fell in attempting to walk, and became increasingly quarrelsome, irritable and irrational, with incontinence and episodes of stupor. Neurologic examination was still negative apart from exaggerated knee jerks, and a lumbar puncture was entirely normal except for an increased globulin content; blood studies and serologic tests were normal. Three weeks before admission, transient aphasia again appeared, and the patient was unable to stand without support. The periods of stupor became more frequent and prolonged, his conduct varying between smiles of apparent recognition, and irrationality and semiconsciousness. At times the patient refused nourishment, becoming noisy and uncontrollable; again, he would lie groining and unresponsive. The temperature swung between 101 and 105°F, he developed a cough without sputum, and on one occasion vomited "coffee grounds with mucus." During the journey to the hospital the patient was very drowsy and at one point developed a marked, transitory respiratory difficulty with cyanosis.

The patient had suffered from typhoid fever fifteen years before admission, and two years before admission his physician had recorded a blood pressure of 184 systolic, 122 diastolic, but at that time he appeared perfectly well. For ten years he had had occasional severe headaches, but had not complained of headache during the present illness. His family was noted for longevity, both the mother and father having died between ninety-five and a hundred of hypertension with cerebral manifestations.

On examination the patient was semicomatose,

restless, moaned occasionally and withdrew his extremities from painful stimuli. His emotions ranged from wild laughter to tears. The pupils were of average size, equal and reacted to light. The retinal vessels and optic disks appeared normal. There was no facial weakness, the neck was rigid (a sign that the nurse had not noticed until their arrival at the hospital). Flexor and extensor tone was increased in the right arm, and the right knee and ankle jerks were more active than those on the left. Sustained ankle clonus was present on the right, with four to five clonic jerks on the left. The plantar reflex on the right was equivocal; on the left it was normal.

In general, the patient was dehydrated, with loose skin, dry mouth and coated tongue; there was a thick ropy posterior pharyngeal discharge. The heart, lungs and abdomen were essentially normal; the blood pressure was 135 systolic, 95 diastolic.

The temperature was 100.5°F, the pulse 100, and the respirations 25.

The urine was normal. The blood showed a red cell count of 4,830,000 with a hemoglobin of 14.5 gm (photoelectric cell technic), and a white-cell count of 13,100 with 92 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 28 mg, the sugar 118 mg per 100 cc, the blood Hinton reaction was negative.

A lumbar puncture gave an initial pressure of 160 mm of spinal fluid. The fluid contained 2 cells per cubic millimeter, and the total protein was 60 mg, the sugar 127 mg and the chlorides 727 mg per 100 cc. A gold sol curve was 0001100000, the Wassermann reaction negative.

X-ray films of the skull showed an area of calcification measuring 4 by 3 by 2 cm. in the left posterior parietal region close to the mid line. This shadow was made up of small circular shadows having the appearance of calcification in blood vessels. The pineal body was not displaced in the lateral views and was not visible in the anteroposterior views. The sella turcica was normal in size and shape, and the bones of the vault appeared normal.

An x-ray examination of the chest was negative.

An electroencephalogram showed abnormal, 3 per-second waves, chiefly on the right side, with most of the slow-wave activity in the right posteroparietal region.

On the fifth hospital day, an operation was performed.

DIFFERENTIAL DIAGNOSIS

Dr. Augustus S. Rose. We can be certain that we are dealing with a patient whose symptoms came from the brain, and that the data are suffi-

cient to permit us to say that the lesion was on the left side. Therefore our differential diagnosis must consider those unilateral lesions which might produce this history and these physical findings. In my differential diagnosis I shall include some infectious process of the brain, dural sinuses or subdural spaces, cerebrovascular disease, subdural hematoma and tumor.

While Dr. Holmes looks over the x-ray films we can briefly review the history. Stripped of the nonessential data, we are dealing with a sixty-two-year-old man with a history of headaches for ten years, who had a period of one month of vague cerebral symptoms followed by a month of progressive signs and symptoms. These were intermittent aphasia, variable consciousness, irrationality, stupor and fever. On physical examination there were coma, dehydration, stiff neck, normal pupils and optic disks, and increased reflexes on the right side, with some increased tone. A slight fever, a moderate increase in the white-cell count and negative serologic tests were also recorded. Lumbar puncture showed a normal pressure and only slight elevation in protein. The skull x-ray film gives an important lead.

DR. GEORGE W. HOLMES: The lesion described can be quite distinctly seen by those of us who are close. It does have very much the appearance of calcification in the walls of blood vessels. It is a little far back and a little high, I think, for the choroid plexus, although it does not look unlike that.

DR. ROSE: Should you say it is in the substance of the brain or on its surface?

DR. HOLMES: I should think it is in the substance of the brain, or in a dilated ventricle.

DR. ROSE: It is not consistent with calcification in a blood clot such as an old hematoma?

DR. HOLMES: No; furthermore, I think that is very rare.

DR. ROSE: There is no evidence of increased pressure?

DR. HOLMES: No.

DR. ROSE: I do not dare ask you whether you think it is a tumor.

DR. HOLMES: It would not do you much good because I could not answer it.

DR. ROSE: First, of the conditions mentioned, an infectious process, such as brain abscess, meningitis, thrombophlebitis of one of the dural sinuses or subdural abscess, can be most easily ruled out. Indeed, the question of infection is raised only because of fever, increased white-cell count and stiff neck. There is no history of an antecedent infection that might have served as a source of an intracranial infection. The duration and the character of the symptoms, the normal cerebrospinal-

fluid pressure and the absence of cells in the spinal fluid are all conclusively against the diagnosis of an infection. The fever and elevated white-cell count may be explained by dehydration, although some other factor is necessary to explain the temperature of 105°F. The stiff neck is also a troublesome matter. In the absence of infection, rigidity of the neck is a sign not infrequently seen in posterior-fossa tumor, but when present is usually associated with increased pressure, and is explained by irritation of the tentorium. In this case, there is neither increased pressure nor evidence for a subtentorial tumor. Possibly it was produced by irritation from above.

Cerebrovascular disease is a "wastebasket" into which this case could easily be placed if we did not carefully consider the nature of the symptoms. By cerebrovascular disease, I imply arteriosclerosis and thrombosis, which are here suggested by the patient's age, blood pressure, intermittent symptoms and relatively normal cerebrospinal fluid. But variable coma, a relatively rapid course and the absence of paralysis or even weakness, although aphasia was present, are strongly opposed to cerebrovascular thrombosis as the primary disease. Furthermore, the x-ray film gives evidence of a lesion, which we must assume is associated with the primary disease, and which must have been present long before the onset of symptoms. We may therefore safely rule out cerebrovascular disease.

Except for the intracerebral calcification and lack of a history of a head injury, we have in this case an almost perfect picture for subdural hematoma; that is, an elderly man with frequent headaches who develops confusion and irrationality followed by stupor and coma. The physical examination shows fewer signs than would be expected from the severe clinical reaction, and although the symptoms suggest increased intracranial pressure, it is not found. These are features commonly associated with chronic subdural hematoma. However, in a case of a hematoma producing symptoms of this severity there should be evidence of pressure, and one might also expect a dilated pupil on one side from compression of the third nerve. But again the x-ray evidence points to a deep intracerebral lesion and is the deciding factor in excluding conditions other than tumor as the primary cause of symptoms.

Having arrived at tumor as the best diagnosis we are left with the question of the type of tumor. This is a difficult question, for it is necessary to find a tumor that grows slowly and yet causes severe symptoms without producing increased pressure. Only the slowly growing tumors contain calcium. The slowly growing tumor as a

rule does not cause coma without pressure. The calcification, as described, is made up of circular shadows. This raises the question of hemangioma. However, a hemangioma would have been present for many years and these symptoms could be produced only by bleeding and we have no evidence for hemorrhage. The location and type of symptoms and the absence of pressure, as well as the x-ray appearance, are against meningioma. Gliomas that produce calcification are the oligodendrocytoma and the astrocytoma. Both may grow slowly. The former is usually very heavily calcified and first causes local symptoms, then pressure. An astrocytoma may contain irregularly placed calcium deposits and infiltrate widely. Therefore, although the x-ray appearance is not what I should expect, I make astrocytoma my first choice.

DR. WILLIAM B. BREED: I am interested in the electroencephalogram, about which I know little or nothing. But according to this report the abnormality is placed on the right side. Is this important? Should we pay any attention to it? Everything else points to the left side.

DR. ROSE: That is why I ignored it.

DR. BREED: Should we continue to ignore the electroencephalogram?

DR. ROSE: In general, I do not believe we have yet acquired sufficient knowledge to interpret the electroencephalogram accurately and adequately.

DR. W. JASON MIXTER: A large posterior left-sided occipitoparietal bone flap was turned down. The dura was reflected upward. The brain appeared somewhat atrophied. There were lakes of spinal fluid around the arachnoid. The vessels were engorged, and many of the arteries, which were large and tortuous, were markedly sclerotic. No mass could be felt anywhere. A ventricular needle was inserted through the cortex pointing toward the location of the mass as shown by x-ray study. The mass was encountered, and then the needle slipped forward into the ventricle. Brownish-yellow fluid was withdrawn at first, and later clear ventricular fluid. It was evident that the ventricle was considerably dilated. An opening was made in the anterior part of the occipital lobe over the site of the exposed mass, and dissection of brain tissue by diathermy was carried down until the ventricle was entered, the funnel being about 3 cm. across on the surface. The ventricle itself seemed normal except for dilatation, and the choroid plexus seemed normal. In the medial portion of the roof of the ventricle could be felt a very hard, irregular mass running forward for about 5 cm., apparently about 2 cm. in width. This was exposed by incising the white matter

about the ventricle. There was very free bleeding about the tumor from moderate-sized arteries and veins. The tumor seemed to be composed of grayish-purple tissue in which large calcified vessels were running. The posterior third was dissected out with considerable difficulty. Bleeding points were controlled with clips and diathermy. After consultation with Dr. Kubik, it was believed that the mass was irremovable in its entirety. The opening into the ventricle was left wide open and the dura closed with interrupted silk sutures. The postoperative diagnosis was probable hemangioma.

DR. CHARLES S. KUBIK: That was the preoperative diagnosis too?

DR. MIXTER: Yes, based entirely on the x-ray findings.

CLINICAL DIAGNOSIS

Left parieto-occipital tumor, probably a hemangioma.

DR. ROSE'S DIAGNOSIS

Astrocytoma, left parieto-occipital region.

ANATOMICAL DIAGNOSES

Hemangioma of the left parietal lobe.
Subdural hematoma, postoperative.
Bronchopneumonia.

PATHOLOGICAL DISCUSSION

DR. KUBIK: The patient died of bronchopneumonia on about the twelfth postoperative day. A hemangioma in the left upper posterior parietal region and also a left subdural hematoma were found at autopsy. I believe the subdural hematoma was postoperative. The membrane was very friable and would, I think, be consistent with a twelve-day affair.

DR. MIXTER: There was no evidence of it at the time of operation. We had a fair exposure of the hemisphere.

DR. KUBIK: The tumor, measuring from 2.5 to 4 cm. in diameter, was on the medial surface in the posteroparietal region of the left hemisphere above and to the inner side of the lateral ventricle. On the surface were innumerable blood vessels like a mass of small fishworms, and leading into the mass were the anterior cerebral and posterior cerebral arteries, both of which were greatly dilated on the side of the tumor while on the other side they were normal. Between the tumor and the superior longitudinal sinus there was a plexus of small vessels that emptied, through a large sinus, into the superior longitudinal sinus, and also what appeared to be arterial branches connecting directly with the superior longitudinal

sinus. These lesions are probably not true neoplasms but developmental anomalies, and may perhaps be first cousins to congenital arteriovenous anastomoses, of which we had an example several years ago. In that case, there were numerous communications between arteries and veins, with tortuosities that never amounted to masses like the one in this case but approached that condition in some places.

DR. ROSE: Was there any evidence of recent hemorrhage?

DR. KUBIK: I did not find any. That is a curious thing about the case. Why did the patient have symptoms if there had been no recent bleeding? The clinical picture was more consistent with the subdural hematoma.

DR. MIXTER: Is it not true that there was a good deal of clotted blood inside these vessels, probably from thrombosis within the tumor?

DR. KUBIK: Yes. It is rather interesting, too, that although this patient had had severe headaches for ten years, which I suppose were related to the hemangioma, he had no headache preceding entry to the hospital.

DR. ROSE: At least he did not talk about it, or could not.

DR. KUBIK: That was the history given by his nurse and by his family physician.

CASE 27202

PRESENTATION OF CASE

First Admission. A fifty-year-old divorced shoemaker was admitted to the hospital complaining of pains in his stomach of two years' duration.

The patient said that he always had been strong and healthy before his present illness. Four or five years before admission, he noted that the ingestion of cold food such as ice cream or ice water immediately precipitated vomiting, the vomitus consisting of recently eaten food and occasionally of coffee-grounds material. There had never been any bright blood. Only cold food had this effect. Gradually these vomiting episodes were preceded by a griping, squeezing pain, which began fairly low in the abdomen and radiated upward to "press on my heart." The patient noted that the pains were worse when associated with hunger, and that they were markedly relieved by the ingestion of warm food. At times these stomach pains disappeared for two or three days, but they then recurred. He was frequently awakened from a sound sleep by pains that caused him to double up; these pains, unassociated with the ingestion of cold food, were described as being griping in character. After a few minutes, the pain disappeared.

The patient also noted gaseous and acid eructations and constipation, but no abnormal stools. He had never had jaundice or hemorrhoids. Four years before admission he weighed 185 pounds, three years later, 155 to 160 pounds, and at the time of admission, 147 pounds. Because of the pain, which had become constant, and because of increasing weakness, he finally had to give up work two months before admission.

The past and family histories were noncontributory except for the occurrence of pneumonia ten years before entry, with complete recovery, and an episode thirty years previously, while the patient was in the Russian army, characterized by chills and fever of two months' duration, which was apparently cured by the frequent ingestion of quinine. He had suffered the usual childhood diseases.

Physical examination revealed a well-developed but somewhat emaciated and markedly anemic man lying quietly in bed in no apparent distress. Examination of the heart was negative. The blood pressure was 130 systolic, 75 diastolic. The lungs were clear. The abdomen was slightly tender on pressure in the right upper quadrant and right mid-epigastrium. No masses or spasm was noted. Rectal examination revealed a firm, slightly enlarged prostate.

Examination of the urine was negative. Examination of the blood showed a red-cell count of 4,000,000 with 60 per cent hemoglobin.

X-ray examination revealed a mottled, irregular filling defect involving the mid-portion of the stomach and extending up toward the cardia and down toward the pyloric end. The walls of the stomach in this region were rigid, and peristalsis was absent. There was no retention of the six-hour meal. The first portion of the duodenum was normal in contour and in the usual position. The six-hour meal had reached the transverse colon.

On the fifth day, a partial gastrectomy was performed. The pathologic report was adenomatous polyp. The patient developed an infected wound, which had to be drained. Six days after operation, he began to vomit and visible peristalsis appeared. Gastric lavage was done twice, and on both occasions there was a large amount of dirty material in the stomach. Because of the apparent intestinal obstruction, he was again operated on and lysis of adhesions was performed. He improved steadily and was discharged on the twenty-first hospital day.

Second Admission (thirteen years later). The patient had been well since his discharge and was followed in the gastrointestinal and tumor clinics.

Four months before the present admission, he began to have sharp pains located in the left lower quadrant and radiating up to the sternum and lateral borders of the ribs and around to the back. These pains occurred while he was ingesting food but one month before admission they became constant and localized in the epigastric region. His appetite remained good, but he noted increasing discomfort at the time of eating. He lost 5 or 6 pounds in four months. He had noted some increase in weakness. For the past two or three years before the second admission, the patient noted nocturia four or five times and increasing difficulty in starting the urinary stream. He had no other complaints.

Physical examination showed a thin patient, with a loose inelastic skin. His teeth were poor. There were several firm, movable, nontender shotty lymph nodes in the right axilla. The peripheral vessels were tortuous and sclerotic. Examination of the abdomen revealed a right upper pararectal scar and a midline upper abdominal scar, in the center of which was a small incisional hernia. There was tenderness without spasm in the left upper abdomen. There was very slight pitting edema of the right ankle.

The urine examination was negative. Examination of the blood showed a red cell count of 3,400,000 with 55 per cent hemoglobin. The stools were dark brown and formed, and showed a ++ guaiac reaction. The serum nonprotein nitrogen was 23 mg per 100 cc, the serum chloride 99.8 milliequiv and the carbon dioxide combining power 29.8 milliequiv per liter, and the serum protein 5.42 gm per 100 cc. X-ray examination of the stomach revealed a large, fungating, ulcerated tumor mass, which occupied the greater portion of the stomach, leaving the fundus and immediate prepyloric region free. The tumor was slightly movable and extended high on the posterior wall, where it probably reached slightly above the cardia. The pylorus opened readily.

On the tenth day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR F DENNETTE AOAMIS. The circumstances of the first admission require little comment. The patient was admitted with a story highly suggestive of some upper gastrointestinal tract disturbance, the roentgenologist demonstrated a gastric lesion, and operation was quite properly performed. We are not told whether the clinicians or the roentgenologist made the preoperative diagnosis. I should not have made it on the basis of the history and physical examination alone, although having been fooled by polyp before, I prob-

ably should have mentioned it in differential diagnosis. I know of no special significance that can be attached to the vomiting immediately after ingestion of cold foods, unless it indicates an unusually irritable stomach. The periodic griping pain, appearing when the stomach was empty and relieved by vomiting or by food, suggests an obstructing ulcer. The night pain also suggests ulcer although characteristically it is described as boring or burning rather than griping. The coffee grounds vomitus and the moderate anemia indicate bleeding, the constipation and loss of weight suggest carcinoma—the latter, however, may have been due to reduction of intake based on fear of eating. The duration of the illness is long for carcinoma. Therefore, without a ray examination to fall back on, my preoperative diagnosis would have been ulcer with obstruction.

The elevation of the nonprotein nitrogen is puzzling, in the absence of any indication of uremia or other sign of kidney impairment, I am inclined to disregard it.

DR TRACY B. MALLORY. All the chemical tests were done postoperatively. The patient developed intestinal obstruction, and that, of course, is what pushed up the nonprotein nitrogen. I shall give you more information about that polyp. The specimen sent to the laboratory showed a freely movable polypoid growth 3 by 4 by 10 cm. That is a large polyp. Microscopic examination showed some degree of atypicity, with papillary growth into the tubules, some hyperchromatic cells, occasional mitotic figures, but no evidence of invasion. The surgical pathologist remarked that the tumor was at the borderline of malignancy, but he was inclined to consider it benign.

A PHYSICIAN. Do polyps cause that much pain?

DR AOAMIS. I suppose one would have to assume that the polyp ever so often worked itself into the pylorus and that the severe griping pain resulted from the effort of the stomach to push it along.

DR MALLORY. Long slender polyps can slip in to the pylorus. This was a broad sessile one, which one would not expect to wander around much.

DR AOAMIS. Then I suppose we must say that polyp per se can cause this kind of pain.

In the second episode, lower abdominal pain again confuses the picture. It might have been due to partial obstruction, caused by adhesions from the previous operations. But since griping did not continue and everything else points to the upper abdomen, we had best look there for the trouble. Events had moved more rapidly this time. Prior to the first admission the patient was sick for five years, on the second entry he had

been sick for only four months. The epigastric pain was constant and not relieved by food; this is not the picture of ulcer. There is nothing to suggest pyloric obstruction. The genitourinary symptoms can be dismissed as incidental; the patient was sixty-three—he had a right to some enlargement of the prostate gland. Physical examination was negative. The blood count and stool examination indicated bleeding. Even without the aid of the roentgenologist, one would be safe in attributing this illness to a gastric lesion. Was it benign or malignant? Did the patient have another benign polyp, an ulcer or a carcinoma? We know that bleeding is common in all three. The character of the pain tends to exclude ulcer. We know that polyps are likely to become malignant. We know that mitotic figures were seen in the tissue removed thirteen years previously, but invasion was not demonstrated. We know that the patient had gone downhill. So that without x-ray I should hazard a diagnosis of carcinoma of the stomach. When we read the report of the roentgenologist, I suppose we must consider the possibility that the ulcerating mass was a polyp. I should still be inclined to make a diagnosis of carcinoma, since ulceration of a benign polyp is not common—that is, ulceration which can be visualized.

A PHYSICIAN: What do you expect from surgery in a case like this?

DR. ADAMS: If the patient had a polyp, it might be removed, or if a carcinoma, a total gastrectomy might prolong life for a while.

DR. MALLORY: A third point always to be considered in such a case is the relief of distressing symptoms for the duration of life. For instance, with carcinoma of the rectum it is often justifiable to resect even in the face of demonstrable metastases in the liver because there may be no other

way of controlling symptoms; one thus gives the patient six months to two and a half years of reasonably comfortable living instead of constant torture. One does not have to feel that a lesion is completely curable to justify operation.

CLINICAL DIAGNOSIS

Carcinoma of the stomach.

DR. ADAMS'S DIAGNOSIS

Carcinoma of the stomach.

ANATOMICAL DIAGNOSIS

Carcinoma of the stomach, with metastases to the regional lymph nodes.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The clinical diagnosis in the wards was carcinoma of the stomach. The patient was explored by Dr. Edward D. Churchill, who found a carcinoma of the mid-portion of the stomach, practically encircling it, with no metastases in the liver but with a few lymph nodes that seemed obviously metastatic along the course of one of the gastric arteries a little farther out than it was possible to carry the resection. On the other hand, the intrinsic stomach tumor was readily resectable, and a subtotal gastrectomy was done. It is presumed that some involved lymph nodes were left behind. The operation was attended with considerable difficulty in its last stages, because the patient had had two previous operations in the upper abdomen and it was very difficult to close the abdominal wound. He left the hospital in about three weeks' time with significant relief from symptoms. He has been in for three follow-up visits and is feeling fine. He is not cured but much more comfortable than he was before operation.

The Journal does not hold itself responsible for statements made by any
author or editor

COMMUNICATIONS should be addressed to the *New England Journal of
Medicine*, 5 Fenway Boston, Massachusetts

Boston hospitals covering anesthesiology, which should be particularly instructive owing to the significant advances that have been made in recent years. No doubt many of the other exhibits will be of as much or more interest, they all deserve particular attention.

The technical exhibits, arranged by medical book publishers, equipment and pharmaceutical houses and other medical service organizations constitute as large a display as has ever been shown at an annual meeting. The physician of today is very dependent on the products or services distributed by all such companies. Books, equipment, drugs and various medical services will be displayed or explained by competent men from the leading firms throughout the country. Members are urged to visit the many booths, both for the information they may acquire, and for the effect it will have on the exhibiting companies. The success of the meeting, from the exhibitor's point of view, is judged on the basis of attendance at his particular space, and a friendly visit to each booth means future assets for the Society.

THE PROBLEM OF ALCOHOLISM

Man has used various drugs throughout the ages to blunt his senses increasing the illusion of pleasure by decreasing the awareness of distress. It seems to me that we are closer to the middle of the road than in most groups one may be abstinent or temperate without being subjected to embarrassing comment. The change in feeling with resulting regulatory laws has been in the main helpful, but it still remains a serious problem. Alcohol is a major cause of insanity, and poisoning from it is the cause of more deaths than many dreaded infectious diseases. Intemperate drinkers may be classed as stable or unstable, and the drinking of the former may be regarded as evidence of disease of the social order, while that of the latter demonstrates disease of the individual. The unstable drinker is particularly susceptible to drinking because he gets so much more pleasure out of alcohol than does the normal individual.

Instability is not the only cause of alcoholic addiction since there are as many unstable men as women in the general population yet there are many more alcoholic men than women. The chronic alcoholic is the result of an unhealthy social custom plus environmental accident plus his instability but a break in any one of these links may save him just as

EXHIBITS AT THE ANNUAL MEETING

The scientific exhibits scheduled for the annual meeting of the Massachusetts Medical Society give promise of the usual high quality and interest. Most of the specialties will be represented, a fact of considerable importance in view of curtailment of the meetings of the various sections. Two exhibits deserve special emphasis. The first is that sponsored by the Regional Committee on Fractures and Trauma of the American College of Surgeons, the Boston Metropolitan Chapter of the American Red Cross and the National Ski Patrol since the first aid treatment of fractures is of timely interest because of the increase in highway and skiing accidents and because of the defense program. The second is an exhibit by sta-

escaping the environmental accident saves many potential victims. . . .

Chronic alcoholics present a greater problem than other drinkers to physicians and health officers, and they are treated by the thousands in public hospitals for acute excesses; they die because of these excesses and from complicating conditions. A large proportion of those who escape premature death go from bad to worse until they become psychotic and find their way into hospitals for mental disease. . . .

The entire problem must be approached without passion or prejudice. We must work with and not against human nature. . . . The harm done by alcohol can be reduced to a minimum by education as to the effects of alcohol, by building up social disapproval of excesses, by making it inconvenient and more expensive to get liquor with a high alcohol content, and by providing more and better hospitalization and less jail treatment for alcoholics. . . . It is not enough to know that some people become drunkards because they are unstable; and that they repeatedly relapse to drink because they are weak. It is necessary to know the nature of their instability and weakness. We should know whether in addition to the predisposing physiologic factor, some people have a special sensitivity to alcohol and if so, what the nature of it is.

The above statements are excerpts from an address by Dr. Thomas Parran, Surgeon-General of the United States Public Health Service, at a symposium of the Research Council on Problems of Alcohol, held in Philadelphia in December, 1940, as a part of the annual meeting of the American Association for the Advancement of Science, and abstracted elsewhere in this issue of the *Journal*. The group, which is engaged in studying the problem of alcoholism in an unbiased scientific manner, could not have made a happier choice of spokesman and keynoter, since Dr. Parran is familiar with the problems, both physical and psychologic, that make the care of the nation's health a matter of greatest importance, along with the care of its finances, its defense and the utilization of its resources. Dr. Parran's attitude betokens a new interest on the part of the federal government, greatly in contrast to the previous concern of federal agencies charged with the enforcement of the Eighteenth Amendment of unhappy memory. The research projects that are now in progress independently and under the sponsorship of the Research Council on Problems of Alcohol lend hope to the possibility that within

the lifetime of even the older readers of the *Journal* alcoholism may take its place along with tuberculosis, syphilis and the various infectious diseases that are now being brought under control. Perhaps this problem, above that of all other diseases, must be attacked by prevention and education rather than by direct treatment. The greatest assistance that every physician can lend is an attitude of open-mindedness and an appreciation of the well-established fact that excessive drinking is a symptom of a basic disorder of personality.

MEDICAL AID TO CHINA

UNITED China Relief, of which the American Bureau for Medical Aid to China is one of the seven participating agencies, has designated May 18 to 25 as China Week. On May 19, Medical Aid-to-China Day, Dr. Robert K. S. Lim, director-general of the Medical Relief Corps of the Chinese Red Cross, will broadcast from China, other broadcasts will be given in cities all over the United States, ambulances in certain key cities will solicit funds, and street drives will be held.

Of the tremendous medical problem the war has created in China and of the gallant efforts of such men as Dr. Lim to meet the problem, probably many physicians are aware, and it is hoped that the medical profession will wholeheartedly support this drive to obtain funds that are so badly needed.

MEDICAL EPONYM

HIRSCHSPRUNG'S DISEASE

Professor Harold Hirschsprung (1830-1916), of Copenhagen, presented to the Gesellschaft für Kinderheilkunde in Berlin, 1886, a report of two cases of "Stuhlträgheit Neugeborener in Folge von Dilatation und Hypertrophie des Colons [Constipation in the Newborn as the Result of Dilatation and Hypertrophy of the Colon]." His paper was printed in the *Jahrbuch für Kinderheilkunde und Physische Erziehung* (27: 1-7, 1888). It was not until November 17, 1889, however, that he specifically described "Die angeborene Erweiterung und Hypertrophie des Dickdarms [Congenital Dilatation and Hypertrophy of the Colon]," in an article contributed to the *Paediatrische Arbeiten*

(78-86, Berlin, 1890), which was published as a *Festschrift* in honor of the seventieth birthday of Edouard Henoch. A portion of the translation follows:

There occasionally occurs in children a congenital marked dilatation of the colon with coincident thickening of its wall—as yet observed only in boys.

The commonest important symptom is difficulty in defecation, beginning immediately after birth and at times associated with enormous distention of the lower abdomen.

It seems that the condition is compatible with continued existence and that occasional cases of habitual stubborn constipation with large abdomen in older children and adults may be due to this congenital affection.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE OF ARRANGEMENTS

The following physicians have consented to act as aides to the Committee of Arrangements at the annual meeting of the Society on May 21 and 22:

Dr. Robert Barker.
Dr. Richard Dwight.
Dr. Roy J. Heffernan.
Dr. Harrison K. Kennard.
Dr. Stanley Kimball.
Dr. John F. McManus.
Dr. R. Bretney Miller.
Dr. Richard S. Nugent.
Dr. Allen G. Rice.
Dr. Frederick Tudor.
Dr. George C. Tully.

EDWARD J. O'BRIEN, M.D., *Chairman*.

SECTION OF MEDICINE

The Section of Medicine calls attention to the following schedule for the round-table luncheon meeting on Wednesday, May 21, at the University Club:

Subject: The Use and Abuse of Drugs in Heart Disease. Dr. Paul D. White, Boston.

12:00-12:45 Preliminary discussion.

12:45-1:30 Luncheon.

1:30-2:00 Question period.

ALBERT A. HONOR, M.D., *Chairman*.

SECTION OF OBSTETRICS AND GYNECOLOGY*

RAYMOND S. TITUS, M.D., *Secretary*
330 Dartmouth Street
Boston

CESAREAN SECTION AND APPENDECTOMY, FOLLOWED BY BRONCHOPNEUMONIA AND DEATH

A thirty-six-year-old para III entered the hospital at term but not in labor, and an elective cesarean section was performed. She had been seen routinely since the fourth month.

The past history showed that the patient had had no serious medical conditions. Her first delivery, twelve years previously, was said to have been moderately difficult, the baby weighing 7 pounds, 2 ounces. The second delivery six and a half years previously was not so difficult as the first, and the baby weighed 8 pounds.

On physical examination, the heart was not enlarged; there were no murmurs. The lungs were clear and resonant; there were no rales. The blood pressure was normal—120 systolic, 60 diastolic. There was no edema. The presentation was normal. Cesarean section was decided on because the patient expressed a desire not to go through labor and because she was "in not too good general health." The anesthetic employed was nitrous oxide, oxygen and ether, which was taken badly. The operation included a low cervical cesarean section, sterilization and appendectomy.

On the second postoperative day, the patient's temperature was 103°F., with a pulse of 104. Bronchial breathing was said to have been heard before death, which occurred on the fourth day after operation, and bronchopneumonia was recorded as the cause of death.

Comment. Cesarean section, even when electively performed, carries with it certain risks; pneumonia is one, sepsis another, and hemorrhage a third. There seems very little medical justification for performing such a hazardous operation on a patient who has had two previous pelvic deliveries. The desire of the patient to be saved the discomfort of labor, in this day of comparative freedom from pain afforded by modern analgesics, should never influence the surgical decision. Furthermore, there is some controversy over the advisability of performing an appendectomy at the same time as a cesarean section. Although a few

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

men consider such an appendectomy a harmless performance, it is not permitted at the majority of obstetric clinics in Boston.

The patient had excellent obstetric care throughout her pregnancy, and there seems to have been no justifiable reason for performing the cesarean section and the appendectomy, which undoubtedly were major factors in the fatal result. Obstetric rules and regulations should follow the routine laid down by the best metropolitan institutions, and the trustees of hospitals should insist that they be followed explicitly.

DEATHS

MURPHY—**FREDERICK P. MURPHY, M.D.**, of Lowell, died April 26. He was in his sixty-second year.

He received his degree from Tufts College Medical School in 1905. Dr. Murphy was a member of the Massachusetts Medical Society, president of the Middlesex North District Medical Society from 1936 to 1937, a member of the American Medical Association and the New England Obstetrical and Gynecological Society.

SWEET—**FREDERICK B. SWEET, M.D.**, of Springfield, died May 10. He was in his seventy-second year.

Dr. Sweet received his degree from Yale University School of Medicine in 1893. He had been a trustee of the Springfield Hospital since 1911, and visiting surgeon since 1904. He was also consulting surgeon at the Mary Lane Hospital in Ware and the Wing Memorial Hospital in Palmer.

Dr. Sweet was a member of the Massachusetts Medical Society, president of the Hampden District Medical Society from 1929 to 1930, a fellow of the American Medical Association, and a member of the American College of Surgeons and the New England Surgical Society, of which he had been a president.

His widow and two daughters survive him.

MISCELLANY

ANNUAL PRIZE SUBSCRIPTION

The annual prize subscription offered by the *New England Journal of Medicine* for the best undergraduate contribution to the *Tufts Medical Journal* has been awarded to Ralph M. Myerson, '42, for his paper "Endometriosis," which appeared in the March, 1941, issue. The paper "Hypoglycemia in the Non-Diabetic" by Henry J. Myers, '41, received honorable mention; it will appear in the May issue of the *Tufts Medical Journal*.

MAINE NEWS

ANNUAL MEETING OF THE MAINE MEDICAL ASSOCIATION

The program for the eighty-ninth annual meeting of the Maine Medical Association, to be held at the Marshall House, York Harbor, on June 22, 23 and 24, is as follows:

SUNDAY, JUNE 22

Golf preliminaries.

4:30 p.m. First meeting of the House of Delegates.

8:30 p.m. Entertainment for the members and their wives.

MONDAY, JUNE 23

9:30 a.m. Group conferences.

12:30 p.m. Luncheon (tables reserved for alumni of various medical schools and members of the Tumor Clinics).

2:00 p.m. Introduction of visiting delegates.

2:00 p.m. Scientific session.

5:00 p.m. Election of president-elect.

5:30 p.m. Second meeting of the House of Delegates.

7:00 p.m. Reception to President and his wife.
Dinner and dancing.
Presentation of fifty-year medals.

TUESDAY, JUNE 24

9:30 a.m. Group conferences.

12:30 p.m. Luncheon (tables reserved for past presidents and county secretaries).

2:00 p.m. Scientific session.

Golf finals.

7:00 p.m. Banquet (dress informal):

Address: Frank H. Lahey, M.D., president,
American Medical Association.

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR MARCH, 1941

DISEASES	MARCH 1941	MARCH 1940	FIVE-YEAR AVERAGE*
Anterior poliomyelitis	1	1	0
Chicken pox	1408	1471	1441
Diphtheria	8	7	14
Dog bite	671	727	740
Dysentery, bacillary	3	36	12
German measles	147	56	235
Gonorrhea	324	308	420
Lobar pneumonia	370	609	744
Measles	3127	1486	2957
Meningococcus meningitis	10	3	17
Mumps	1349	866	1326
Paratyphoid B fever.....	3	11	4
Scarlet fever	651	608	1141
Syphilis	462	501	540
Tuberculosis, pulmonary.....	318	218	277
Tuberculosis, other forms.....	33	20	35
Typhoid fever	3	3	5
Undulant fever	6	5	3
Whooping cough	969	644	920

*Based on figures for preceding five years.

RARE DISEASES

Anterior poliomyelitis was reported from: Framingham, 1; total, 1.

Diphtheria was reported from: Auburn, 1; Boston, 3; Fall River, 1; Malden, 1; Newburyport, 2; total, 8.

Dysentery, bacillary, was reported from: Boston, 1; Danvers, 1; Southborough, 1; total, 3.

Infectious encephalitis was reported from: Agawam, 1; Springfield, 1; total, 2.

Malaria (therapeutic) was reported from: Foxboro, 1; total, 1.

Meningococcus meningitis was reported from: Barre, 1; Boston, 2; Brockton, 1; Dartmouth, 1; New Bedford, 3; Ware, 1; Winthrop, 1; total, 10.

Paratyphoid B fever was reported from: Adams, 1; Belmont, 1; Peabody, 1; total, 3.

Pfeiffer bacillus meningitis was reported from: Worcester, 1; total, 1.

Rocky Mountain spotted fever was reported from: Northampton, 1; total, 1.

Septic sore throat was reported from: Amesbury, 3; Ashland, 1; Beverly, 2; Boston, 3; Cambridge, 1; Chicopee, 1; Concord, 2; Fall River, 2; Lynn, 2; Malden, 1;

Medford, 2, Millbury, 1, Monson, 1, Waltham, 1, total, 23
Trahoma was reported from Arlington, 1, Boston, 1,
Peabody, 1, total, 3

Trichinosis was reported from Boston, 1, total, 1
Typhoid fever was reported from Holyoke, 1, Spencer, 1, Winthrop, 1, total, 3
Undulant fever was reported from Boston, 1, Leominster, 2, Somerset, 1, Westford, 2, total, 6

The first case of anterior poliomyelitis for the year was reported in March

Chicken pox, diphtheria, bacillary dysentery, meningococcus meningitis and tuberculosis (other forms) were reported below the five year averages

The number of cases of dog bite increased over the first two months of this year, but it is the lowest reported for the month since 1934

Although German measles was reported below the five year average, more cases were reported than in any corresponding month since 1936

Lobar pneumonia was reported at a record low figure for the month

Scarlet fever increased, although it was reported below the five year average.

Whooping cough was reported above the five-year average.

Typhoid fever and paratyphoid fever showed low incidence.

Measles, which has climbed steadily since October showed a sudden upswing in March

There was a slight upward swing of undulant fever

CORRESPONDENCE

MEDICAL STUDENTS IN RELATION TO THE SELECTIVE SERVICE ACT

To the Editor I believe that in carrying out the provisions of the Selective Service Act we should do well to bear in mind the spirit as well as the letter of the law—at times even shading the latter in favor of the former. Our aim is speed and efficiency in preparedness. When immediate speed may sacrifice ultimate efficiency, we should prefer the latter.

The question of medical school students is one worthy of careful scrutiny. A medical man spending one year to become a soldier would be of no added value to his country since he would never be used in that capacity—hence, a waste of national funds.

If the students now in a Grade A medical school are removed for defense training, the school will be gradually depleted of its best men. It must either admit men of less ability, resulting in a lowered standard of physicians for army and civilian needs, or refuse to replace them and so limit the number available. Both alternatives affect ultimate efficiency and do harm to the nation.

I have said a year spent in military camp by a medical man is wasted to the country because he will not be used as a soldier. A student becomes of less value to the profession and the nation in so far as his training is interrupted. From discussions with others I learn that, if taken for defense training, some students will not return to the medical profession at all first, because of the expense, secondly, because the six or eight years of further training are already long and adding another year makes this long period prohibitive.

Our best medical schools are unsurpassed anywhere. Students are selected on the basis of marked aptitude and about one out of eight or ten applicants is accepted. These men show promise of supplying our future needs in all branches of medicine and surgery.

I am told that the average IQ of the selective service men at one of our largest camps is extremely low. With less than a high school education, it takes one year to make a soldier. It takes ten years for a high school graduate to become a good doctor, and thirteen to become a specialist.

This is the age of scientific warfare. Men in training for specialized work in this and other occupations essential to preparedness should not be hindered, on the contrary, every precaution should be taken to see that their training is completed as soon as possible.

A Memorandum to All State Directors (1-10), dated March 7, 1941, from the National Headquarters of the Selective Service System explains in further detail what discretionary powers the local board may exercise. Deferment in Class II A is permitted where the activity for which the registrant is in training or preparation is one essential to the national health, safety or interest, and the registrant is found to be a necessary man. Group deferments may not be made. 'The period of deferment in Class II A may not exceed six months, but such deferment may be renewed from time to time if the local board finds that such continuance is justified under the regulations.' In other words the local board must consider all the evidence submitted in connection with each individual case and must decide each case on its particular facts.

Since writing the above I have learned something of the English point of view (*Science*, April 4, 1941). "Medical students in England are not subject to draft." Extraordinary precautions are taken to ensure uninterrupted preparation. To this end some of the students are being sent to this country and Canada. I quote, "A break in the chain of medical teaching in any country spells disaster for the coming generation."

Finally from Washington comes the last bit of evidence. The Murray Bill—aimed at exempting medical students from service until they are thoroughly trained—has been defeated. Strangely ironic is the President's appeal for one thousand doctors to go at once to England, so soon on top of the defeat of that bill. Send them by all means since they are so sadly needed but in the face of this conclusive proof of the importance of trained physicians in time of war we are deliberately inviting the same disaster by cutting down our own future supply!

FRANCIS G. BARNUM.

1776 Beacon Street,
Brookline, Mass

REPORTS OF MEETINGS

HARVARD MEDICAL SOCIETY

A regular meeting of the Harvard Medical Society was held at the Peter Bent Brigham Hospital on February 11, with Dr. Soma Weiss presiding.

The first case, presented by the medical service, brought up the differential diagnosis between pneumonia and lung abscess. The patient had been given sulfathiazole treatment. In discussing the case, Dr. Maxwell Finland stated that the signs and symptoms more or less resembled those of a virus pneumonia but that the x-ray appear

ance was solid rather than flaky. The rash across the bridge of the nose closely simulated that of sulfathiazole, which has also caused episcleritis in a few cases and in which the skin lesions are marked on the elbows and knees, as in erythema nodosum. Dr. Merrill C. Sosman described the roentgen findings in virus pneumonia as being more of a diffuse haze similar to that of congestive failure. Dr. Weiss cited two cases of staphylococcal pneumonia treated with sulfathiazole for eight or nine days with persistent fever, which decreased when chemotherapy was stopped. Dr. Finland stated that long-standing fluid is often sterile and that adhesions may simulate empyema by x-ray study.

The second case, presented by the surgical service, was that of a middle-aged woman with a complicated past history whose operation for cholecystitis was delayed five days by an upper respiratory infection. Her post-operative course was uneventful until the fourteenth day, when she had a chill, severe chest pain, a dry painful cough, a fever of 102°F. and some tenderness of the left leg. There were respiratory difficulty and hemoptysis, and the sputum revealed Type 29 pneumococcus. The signs remained unchanged until the third day, when sulfathiazole therapy was instituted and gradual improvement began. Dr. Elliott C. Cutler briefly discussed post-operative pulmonary complications. The most frequent immediate problem is that of atelectasis, whereas, later, embolic phenomena are commoner, as in this case. Dr. Cutler considered it wise to employ the sulfonamides more generally in pulmonary infarction to ward off incipient secondary infection. Dr. Finland stated that the higher types of pneumonia are often from the throat and may not be significant, although secondary infection is very common in such cases as the one described above. It has been found that early postoperative pneumonias have significant pneumonia types and bacteremia about half as often as true lobar pneumonias, so that at least a part of them are true pneumonias that are incidental to the operation.

The speaker of the evening was Dr. Maxwell Finland, of the Boston City Hospital, whose subject was "Treatment of Pneumonia." As an indication of what may be expected among the armed forces during the present war, the speaker cited statistics among the African mine workers, whose condition and environment can certainly be no better than those of our troops. In this group the mortality has dropped from 13 per cent in a period from 1934 to 1937 to 6 per cent in 1938, following the introduction of sulfapyridine, and to slightly over 2 per cent in 1939. Although the results at an institution like the Boston City Hospital cannot be improved so markedly, it is possible by well-controlled observations on a large series of patients to evaluate the relative merits of drugs and to determine the status of specific anti-pneumococcus serum. On the whole, one should use the easiest, safest and cheapest method of treatment, but should be prepared to use auxiliary methods in any case in which it may significantly improve or cure an otherwise lost patient.

It was emphasized that there are always drug failures when enough cases are observed. In the first season of sulfapyridine at the Boston City Hospital the mortality with serum was only 13 per cent, as compared with that of 18 per cent for chemotherapy and 24 per cent for combined treatment. Most statistics failed to show this favorable result with serum because it is used either not enough or not well enough. More of the sick patients receive the combination treatment because of drug failures,

which would increase the mortality of the drug-treated patients if properly interpreted. The statistics at the Boston City Hospital for the last three years were essentially the same except in the increase in the number of patients treated and the significant lowering of the mortality with sulfathiazole treatment. However, when the statistics were broken down in regard to bacteremia, age, number of lobes involved and so forth, it was found that the results in each group were identical, regardless of the drug used. Since all data now indicate that the drugs are equally effective in comparable cases, the ease and safety of administration become important. In this regard sulfathiazole results not only in less nausea and vomiting than sulfapyridine, but what is more important, the severity is far less. Relapse is also much less frequent, and this may be attributable to the early discontinuance that is so often necessary with sulfapyridine. Urinary complications are about the same but may be decreased when it is learned that the circulating blood levels do not need to be so high. Anemia and leukopenia occur slightly less often with sulfathiazole, whereas drug fever and rash occur three times as often with this drug, sometimes even after it has been omitted. The distinctive rash of sulfathiazole has been described above. It was concluded, therefore, that although sulfathiazole is not definitely less toxic, it is much easier to administer and therefore becomes a choice when pleasing the patient is so important.

The drug level is usually considered best at 4 or 5 mg. per 100 cc., but many good results have been obtained with lower levels. The favorable response with these variable and low levels may be explained by the fact that the bacteria are often either of low virulence or in small numbers so that even less than 1 mg. per 100 cc. is effective, especially if a medium is free of inhibiting substance. The newest sulfonamide, a guanidine compound, has a more sustained and higher level in the blood, owing to a lesser degree of acetylation, and all toxic symptoms seem less severe. Preliminary results seem to indicate that it is at least as effective as the other drugs.

The status of specific serum therapy has now become difficult to evaluate because of the availability of the comparatively easily administered drugs. Combination therapy apparently offers the best results both experimentally and from what few clinical data are at hand. Owing to its earlier action, serum may be advantageous in the more serious cases, such as those in the aged, those with bacteremia and those in which several lobes are involved. Serum may decrease the numbers of bacteria to a level where the drug may be effective. It is probably also beneficial in cases that fail to respond to chemotherapy within forty-eight hours, for the bacteria not killed at that period have become acclimated to the drug and are no longer amenable to such treatment. It is important to realize that in some cases serum is ineffective when used late, and that one should probably attempt to evaluate the cases early, so that serum may be given then if it is necessary.

In conclusion, Dr. Finland briefly discussed the recent respiratory epidemic, in which many cases of pneumonia arose as a complication. The initial attack seemed to be characteristic influenza often with a negative chest examination. There was a high incidence of staphylococcal pneumonia with bacteremia in some and empyema in others, with a definite tendency toward spontaneous cure. There were many cases of persistent sterile effusions; others went on to abscess formation. Roentgenograms were variable, revealing consolidation or rarefaction, or

similar to the lesions of virus or staphylococcal pneumonia. The discussion was opened by Dr John Enders, who described the isolation of a virus from uncomplicated cases of influenza that had a typical response in ferrets similar to that of Type A. Dr Joseph H Pratt stated that there had been only three deaths in 89 patients at his clinic, two of these being patients with chronic alcoholism and the other an eighty-year-old cardiac patient. Dr Wald S King presented statistics from the Massachusetts General Hospital revealing that the mortality for the preceding introduction of chemotherapy was less than that of the past year. Results from the Montreal General Hospital in 100 cases treated with sulfapyridine showed a 7 per cent mortality. They have also experienced the same staphylococcal pneumonias following the 1918 influenza epidemic.

BOSTON ORTHOPEDIC CLUB

At the regular meeting of the Boston Orthopedic Club was held on February 17, with Dr Robert J Joplin presiding. W L Aycock spoke on "The Epidemiology of Polio Myelitis." In introduction, he remarked that many theories have been advanced because of the lack of an adequate single explanation, and that the tendency is to offer the most bizarre ones. Since observations on his disease are limited by Nature and most series are small, generalizations are apt to be drawn from limited variations and contradictory facts appear.

It was emphasized that the distribution patterns of the virus and the paralytic form of the disease are not necessarily the same. The virus is widespread, as in all contagious diseases. Dr Aycock deprecated the tendency toward emphasizing the method of spread and implicating the gastrointestinal tract. The mere presence of an organism does not necessarily indicate its importance, and finding of the tubercle bacillus or the measles virus in the feces does not mean that this is their mode of transmission.

Paralysis is limited, irregular and selective, despite the widespread occurrence of the virus of poliomyelitis. Therefore, something in the person exposed probably determines in large measure who shall be paralyzed. Dr Aycock discussed various selectivities. Warm climates and seasons apparently decrease the incidence of paralysis despite the same prevalence of the virus as shown by immunity studies. This is a physiologic rather than an anatomic selectivity. That there is some inherent familial deficiency seems to be borne out by the higher incidence of affected families than in the general population and the frequent recurrences. This is in marked contrast, for example, to measles. The possibility of an endocrine factor is suggested by the higher incidence of paralysis in the Frohlich type of person. Such patients, although of that habit at the time of the attack, may develop immunity of that distribution at puberty. Many observers do not agree with this observation, which is a clinical one.

Another argument in favor of an endocrine factor is the high incidence of paralysis during pregnancy. This is also indicated by a mucous-membrane susceptibility, which is supported by other observations, for the endonervous system involved in pregnancy are known to affect the mucification of mucous membrane. Long in Detroit indicated that there were more than four times as many cases of paralysis during pregnancy as would be expected from statistics. Another observation in favor of a susceptible mucous membrane is the relation of bulbar paralysis to operative tonsillectomy and adenoidectomy. The oc-

currence on the seventh to the fourteenth day postoperatively fits well with the supposed incubation period of poliomyelitis. At the Children's Hospital, of 400 cases of spinal paralysis only 2 occurred following adenoidectomy, whereas 17 of 132 cases of bulbar paralysis occurred following tonsillectomy.

In experimental primates it has been found that castrates treated with estrin become paralyzed early, if at all, and that the incidence in this group is definitely lower than in the nontreated group, who all develop paralysis. In human beings there is an elevated urinary estrogen in pregnancy, but an increased excretion does not indicate an increased utilization of hormone. Furthermore, the urinary estrogen levels are higher, no matter how separated, in all cases of poliomyelitis.

Dr Aycock stated that none of the three usual methods of control are feasible. The disease cannot be checked at its source when the reservoir is the entire population. Spread can hardly be prevented when human intercourse is the only known method of spread. Vaccination was held nonfeasible when an entire population must be vaccinated and the incidence of paralysis at most is only one in a million. Furthermore there will probably never be a safe vaccine. Exposures cannot be limited or accurately judged in comparison with other dangerous diseases such as rabies.

The discussion was inaugurated by Dr Frank Ober, who emphasized the occurrence of multiple cases in families, particularly the less severe, abortive cases. Thirty per cent of so-called abortive cases in Vermont were subsequently found to have a facial paralysis—evidence that more than the limbs should be examined. In regard to climate, Dr Ober is not so sure it is not dietary habits that play a role—possibly vitamin B. For there has been an inadequate diet in Vermont and the South. It is interesting that in a southern town of 60,000 population where there was said to be no poliomyelitic paralysis, Dr Ober was able without advance notice to round up 11 cases. The finding of so many endocrine types at the Children's Hospital had led him to believe that a certain physiologic pattern may develop paralysis.

Dr Moses H Lurie discussed the susceptibility of the nasopharyngeal mucous membrane to the poliomyelitic virus. He did not consider estrogens beneficial in the treatment of atrophic rhinitis. He has observed that 60 per cent of the patients who develop post-tonsillectomy paralysis have the bulbar type. It is well known that the mucous membranes are not intact for thirty days post-operatively. In cases of paralysis following vaccination, the region of the cord affected was that supplied by the nerve at the injection site. Since the glossopharyngeal, vagus and spinal accessory nerves are essentially one system—the nucleus ambiguus—it is conceivable that the virus travels along the first of these and affects the whole system. Therefore, tonsillectomy is not advocated during an epidemic because of the danger of bulbar rather than spinal paralysis. It was stated that the incidence of paralysis is probably no greater than that of other infectious diseases.

Dr Aycock concluded the meeting by emphasizing that vaccination is not feasible in such a usually innocuous disease. In fact the disease itself is really a successful vaccination since only an occasional person develops paralysis of the many who are exposed. In contradiction to the diet theory he pointed out that only certain Vermont families develop paralysis where all eat the same food, whereas members of a family develop the condition despite diet living conditions and geographic differences.

NOTICES

BOSTON CITY HOSPITAL

There will be a staff clinical meeting of the Boston City Hospital on Friday, May 23, at 12 m. in the Cheever Amphitheater, Dowling Building.

PROGRAM

- The Peculiarities of Disease in Children. Dr. James W. Redmond.
 The Neurological Aspects of Pediatrics. Dr. Eli Friedman.
 Dermatological Conditions in Pediatrics. Dr. Francis J. Wenzler.
 Borderline Conditions, Medical and Surgical, in Pediatrics. Dr. John C. Faherty.
 The Anemias in Children. Dr. Eugene F. Callanan.
 Allergy in Children. Dr. Abraham N. Caplan.

SOUTH BOSTON MEDICAL SOCIETY

The thirty-sixth annual meeting of the South Boston Medical Society will take place on Monday, May 19, at the Harvard Club, Boston.

PROGRAM

- 6 p.m. Business meeting.
 7 p.m. Dinner.
 Dr. Chester S. Keefer will speak on "The Modern Treatment of Meningitis."

Reservations for the dinner should be made by Saturday, May 17, and should be sent to Dr. J. Charles Seymour, secretary, 534 Broadway, South Boston.

NEW ENGLAND SOCIETY
OF PHYSICAL MEDICINE

The annual business meeting of the New England Society of Physical Medicine will be held at The Copley-Plaza on Wednesday, May 21, at 5 p.m. Reports of officers and committees will be presented, and officers for the ensuing year will be elected.

UNITED STATES CIVIL
SERVICE EXAMINATIONS

- Senior Medical Officer, \$4600 a Year
 Medical Officer, \$3800 a Year
 Associate Medical Officer, \$3200 a Year

The United States Civil Service Commission has announced open competitive examinations to fill medical-officer positions in the United States Public Health Service and Food and Drug Administration, Federal Security Agency; Veterans Administration; Civil Aeronautics Authority, Department of Commerce; and Indian Service, Department of the Interior. Applications must be filed with the United States Civil Service Commission, Washington, D. C., and will be rated as received until further notice.

Applicants must have graduated with an M.D. degree from a recognized medical school, and must have had professional experience in one of the following optional branches: aviation medicine; cancer research; cardiology; dermatology; eye, ear, nose and throat (singly or combined); general practice; industrial medicine; internal medicine and diagnosis; medical pharmacology; neuro-

psychiatry; pathology; bacteriology and roentgenology (singly or combined); public health; surgery; tuberculosis; and urology. For some positions in the Veterans Administration applicants for associate medical officer, paying \$3200 a year, need not have had experience other than one year of internship. Applicants for the associate grade must not have passed their fortieth birthday, and for the other two grades must not have passed their fifty-third birthday.

Full information regarding the examinations and the application forms may be obtained from the Secretary, Board of United States Civil Service Examiners, at any first-class or second-class post office, or from the United States Civil Service Commission, Washington, D. C.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING
SUNDAY, MAY 18

MONDAY, MAY 19

- 12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.
 6 p.m. South Boston Medical Society. Harvard Club, Boston.

TUESDAY, MAY 20

- *9-10 a.m. Clinicopathological conference. Drs. C. S. Keefer and H. E. MacMahon. Joseph H. Pratt Diagnostic Hospital.
 *12 m. Certain Practical Aspects of Blood Disorders as Seen by the General Practitioner. Dr. Henry Jackson, Jr. South End Medical Club, Headquarters of the Boston Tuberculosis Association, 534 Columbus Avenue, Boston.
 12:15-1:15 p.m. Clinicorontgenologic conference. Peter Bent Brigham Hospital amphitheater.

WEDNESDAY, MAY 21

- Annual meeting, Massachusetts Medical Society. The Copley-Plaza, Boston.
 *9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
 *12 m. Clinicopathological conference. Children's Hospital.
 3 p.m. Massachusetts Medico-Legal Society. The Copley-Plaza. State salon.
 5 p.m. New England Society of Physical Medicine. The Copley-Plaza, Boston.

THURSDAY, MAY 22

- Annual meeting, Massachusetts Medical Society. The Copley-Plaza, Boston.
 *9-10 a.m. Extrarenal Azotemia. Dr. Emanuel Ginsburg. Joseph H. Pratt Diagnostic Hospital.

FRIDAY, MAY 23

- *9-10 a.m. Some Current Problems in Gastrointestinal Surgery. Dr. Richard Warren. Joseph H. Pratt Diagnostic Hospital.
 12 m. Boston City Hospital, staff clinical meeting. Cheever Amphitheater, Dowling Building.

SATURDAY, MAY 24

- *9-10 a.m. Hospital case presentation. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.

*Open to the medical profession.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Pharmacology of Anesthetic Drugs A syllabus for students and clinicians By John Adriani, M.D., instructor in anesthesia, New York University College of Medicine, and assistant visiting anesthetist, Bellevue Hospital 4th, cloth, 86 pp., with 102 illustrations Springfield, Illinois Charles C Thomas, 1941 \$3.50

Help Your Doctor to Help You A series of five medical books *Gastric or Duodenal Ulcer*, 53 pp., *Gallstone and Disease of the Gallbladder*, 41 pp., *Colitis*, 30 pp., *Food Allergy*, 50 pp., *Sick Headache or Migraine*, 37 pp. Ed. statistical Board Dr Walter C Alvarez, editor in-chief, Dr George Blumer, Dr Logan Glendening, Dr Irving Cutler, Dr Howard W Haggard, Dr Rudolph Matas, Dr Charles W Mayo, Dr George R Minot, Dr John H Stokes and Dr George H Whipple 12th, cloth New York Harper and Brothers, 1941 95c each

How to Prevent Gout By Israel Bram, M.D., medical director, Bram Institute for Gout and Other Glandular Disease 8th, cloth, 182 pp., with 21 illustrations New York E P Dutton and Company, Incorporated 1941 \$2.00

Textbook of Pediatrics By J P Crozer Griffith, M.D. Ph.D. emeritus professor of pediatrics, University of Pennsylvania, consulting physician to the Children's Hospital Philadelphia, and consulting physician to St Christopher's Hospital for Children, consulting pediatricist to the Woman's, the Jewish, and the Misericordia hospitals, and A Graeme Mitchell, M.D., B.K. Rachford Professor of Pediatrics, College of Medicine, University of Cincinnati medical director and chief of staff, Children's Hospital of Cincinnati, director, Children's Hospital Research Foundation, and director, Pediatric and Contagious Services Cincinnati General Hospital Third edition, revised and reset. 8th, cloth 991 pp., with 220 illustrations and 66 tables Philadelphia W B Saunders Company, 1941 \$10.00

Endocrinology The glands and their functions By R G Hoskins, Ph.D., M.D., director of research, The Memorial Foundation for Neuro-Endocrine Research, and research associate in physiology, Harvard Medical School 8th, cloth, 388 pp., with 14 illustrations New York W W Norton and Company, Incorporated, 1941 \$4.00

Neurology Lectures for medical students and general practitioners By Knud H Krabbe, M.D., chief physician Department of Neurology, Kommunehospitalet, Copenhagen 8th, paper, 387 pp., with 4 illustrations Copenhagen Denmark Einar Munksgaard, 1941 \$12.00

Fundamentals of Dermatology By Norman Tobias, M.D. senior instructor in dermatology, St Louis University, assistant dermatologist, Firmen Desloge and St. Mary's hospitals, and visiting dermatologist, St Louis City Sanatorium and Isolation Hospital 12th, cloth, 497 pp., with 143 illustrations Philadelphia J B Lippincott Company, 1941 \$4.75

Cardiac Classics A collection of classic works on the heart and circulation with comprehensive biographic accounts of the authors Fifty-two contributions by fifty-one authors By Frederick A Willius, M.D., M.S. (med.), chief, Section of Cardiology, The Mayo Clinic, and professor of medicine, The Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota, and Thomas E Keys, A.B. M.A., reference librarian, The Mayo Clinic 4th, cloth, 858 pp., with 102 illustrations St Louis The C V Mosby Company, 1941 \$10.00

Transactions of the American Association of Genito-Urinary Surgeons Fifty-second annual meeting held at Williamsburg Virginia June 20 21 and 22 1940 Volume XXXIII 8th paper, 314 pp., with 123 illustrations and 18 tables St Paul Minnesota The Bruce Publishing Company, 1941

BOOK REVIEWS

Atlas of Electroencephalography By Frederic A Gibbs, M.D. and Erna L Gibbs Fth, cloth, 221 pp., with 18 figures and 102 plates Cambridge, Massachusetts Lew A Cummings, 1941 \$7.00

If there were a hit parade of medical publications, this volume would soon warrant a place high on the list. There are few, if any, authors who can write more authoritatively on electroencephalography, for the labors of Dr and Mrs Gibbs have been foremost in raising the technique and application of the field from obscurity to a place where it is one of the most valuable diagnostic techniques available to the neurologist and neurosurgeon. The physical make-up of the book is impressive at first glance, and as one goes between the covers, its importance becomes increasingly evident.

An interesting format has been employed. Sample electroencephalographic tracings occupy the right page, with their interpretation and comment opposite them on the left in one column, another column on the left page carries the text. The work is dedicated to Dr Hans Berger, father of electroencephalography, and acknowledgment is made in the preface to other workers in the field, to the technical and engineering staff who developed the equipment and to the co-operating institutions from which the material for the tracings was obtained. Enough tracings are reproduced so that the cortical activity for ten seconds or longer can be followed. The records from three or more leads are included, usually the frontal, the parietal and the occipital, unless some particular feature makes a deviation from this practice preferable.

A great many normal records are included for various ages, during sleep and under other more or less standardized conditions. There are, of course, a large number of tracings from patients with various types of epilepsy and in various stages of seizures. The 'interseizure' records are especially interesting, since it is relatively seldom that a diagnostic tracing can be obtained during a convulsion unless the patient is hospitalized. The characteristic changes during hyperventilation and under the effects of low oxygen tensions are well demonstrated. Typical records from patients with birth injuries, meningitis and encephalomalacia multiple sclerosis, cerebral arterio-sclerosis, migraine and chorea are included, and in each case the characteristic features are described. Perhaps the tracings from brain tumor and cerebral hemorrhage localization studies are most interesting aside from those of convulsive type.

The history of electroencephalography, the activity of the cortex and its similarity to that of other tissues are carefully discussed in the text. The technic is described sufficiently, so that a reader who is unfamiliar with the procedure can become oriented. The authors state that the purpose is not to present a textbook but to furnish eye-training, so that a person may be able to recognize the range of the normal activity and recognize obvious mass abnormalities, as well as to present enough information to make the figures understandable. It appears that they have succeeded in these aims and have done a great deal more than that. The bibliography is complete and comprehensive. The book will be especially useful for teaching and reference purposes, since no other work of its type is available.

A Manual of Embryology: The development of the human body. By J. Ernest Frazer, D.Sc. (Lond.), F.R.C.S. (Eng.). Second edition. 8°, cloth, 523 pp., with 282 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$9.00.

The author retains, in this new edition, the plan originally adopted: to give the student some sort of connected mental picture of the developing embryo, rather than a patchy series of discrete descriptions of the formation of organs. There are few changes in the text, a few new drawings have been introduced, and the discussion of the fetal circulation has been recast. Teachers would do well to draw attention to this book.

Bailey's Text-Book of Histology. By Philip E. Smith, Ph.D., Russell L. Carpenter, Ph.D., Wilfred M. Copenhagen, Ph.D., Charles M. Goss, M.D., and Aura E. Severinghaus, Ph.D. Tenth edition. 8°, cloth, 764 pp., with 448 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.00.

Here is an excellent textbook of histology. As in previous editions, the five authors have succeeded well in correlating structure with function and in discussing the physiologic significance of the structures described. The book is enriched with many fine illustrations, and the references at the end of each chapter should adequately meet the needs of students who desire to carry out collateral reading on any topic. In this edition, two new chapters have been added—one on morphogenesis, and the other on the organization of nervous tissues. The chapter on nervous tissues has been entirely rewritten, and all the other chapters have been revised.

Bone Graft Surgery in Disease, Injury and Deformity. By Fred H. Albee, M.D., LL.D., Sc.D. Assisted by Alexander Kushner, M.D. 4°, cloth, 403 pp., with 297 illustrations. New York: D. Appleton-Century Company, Incorporated, 1940. \$7.50.

A work sponsored by a pioneer in bone-graft surgery demands attention. The field has been thoroughly covered, and the presentation of the material with the excellent illustrations leaves little to be desired. The introductory discussion of the fundamental principles underlying the grafting of bone is clearly stated. Then follows a chapter setting forth the armamentarium essential to the attainment of the best results in the practice of the art. Anyone who has had any experience with the various technics knows that success depends on the possession of proper tools and long practice in their use. It is beyond question that many failures are to be traced to the lack of necessary equipment and of adequate technical skill.

Minute directions are given for the application of grafting technics to the many conditions for which its aid has been invoked—from spinal fusion for many pathologic and traumatic conditions and lesions at and about the hip joint; to ununited fractures, repair of skeletal defects, plastic bone surgery, arthrodesis and bone block. One can subscribe to all that has been said about the perfection of the technics described without agreeing with the author's enthusiasm in advocating these methods in all the conditions in which he champions their employment.

The Clinical and Experimental Use of Sulfanilamide, Sulfapyridine and Allied Compounds. By Perrin H. Long, M.D., and Eleanor A. Bliss, Sc.D. 8°, cloth, 319 pp. New York: The MacMillan Company, 1939. \$3.50.

This is a complete treatise on the clinical and experimental use of sulfanilamide and allied compounds at the Johns Hopkins Hospital. No one in this country has had a wider experience or done more in the experimental field to develop the use of these drugs. The book is a fundamental text. It is a thorough survey in every detail. It has already become a classic contribution to the subject.

Practical Handbook of the Pathology of the Skin: An introduction to the histology, pathology, bacteriology and mycology of the skin with special reference to technique. By J. M. H. Macleod, M.D., F.R.C.P. (Lond.); and I. Muende, M.B., B.Sc. (Lond.) Second edition. 8°, cloth, 415 pp., with 27 colored and 125 black-and-white illustrations. New York: Paul B. Hoeber, Incorporated, 1940. \$9.00.

The first edition of this handbook, published in 1903, became so popular that it was soon out of print. Since then dermatologists have repeatedly requested a second edition, and this present volume of Macleod's, assisted by Muende, should have the same popularity. It presents the subject of pathologic changes in the skin very clearly and briefly. Practically all recent advances are incorporated in this small volume, containing only a little over four hundred pages. The arrangement is of particular value to the students of dermatology.

There is a discussion of the histology and pathology of the various layers of the skin, beginning with the epidermis as a whole and taking up the individual elements that make up these layers. The corium as a whole is then described, before considering its individual components. The skin appendages are then discussed. The various technical methods are briefly outlined, describing the origin and use of special stains.

There are excellent color and black-and-white photographs to illustrate the text. The experience of long years of teaching is demonstrated by the excellent brief reviews outlined at the end of various sections of the book. The chapter on hair and its pathology is well worth reading.

The authors have failed to mention a few advances, such as the method of studying heavy-metal pigmentation of the skin by the darkfield method, the picture of hematochromatosis and the causative factors of Pinta. The chapter on fungous infections of the skin, although brief, contains sufficient information for the average dermatologist who is not doing special work in mycology.

The authors should be congratulated on their excellent text, which should be in the libraries of all students and practitioners of dermatology.

MASSACHUSETTS MEDICAL SOCIETY

THE ROLE OF THE PHYSICIAN IN A COMPETITIVE SOCIETY*

A WARREN STEARNS, M.D.

BOSTON

Know then thyself, presume not God to scan
The proper study of mankind is man
Pope *Essay on Man* (Epistle II)

THE place of the physician in the community has been fixed by long years of tradition. In primitive society, and in remote history, he was a sort of conjurer or magician called upon in times of great calamity or dire distress as an intermediary between the supernatural and the natural. He has developed throughout history, oftentimes some what ahead of contemporary civilization, and has emerged from the realms of magic, superstition, conjecture and belief, largely through the channels of biology, until today he stands as the exponent of the scientific method as related to human welfare. For many years, through the ever unfolding knowledge of anatomy, physiology and pharmacology, he sought to alleviate suffering by treating the ills with which he found his patients afflicted. His task had largely to do with the treatment of individuals. As medicine took on more and more of a scientific aspect, it is only natural that there should have developed special interests, and thus we find certain physicians whose propensities led them to devote their lives more and more to research and scholarship, they have tended to associate themselves with medical schools. Others very early saw a gain to human welfare in preventive medicine, they therefore occupied themselves in developing the field of sanitation and have tended to occupy posts in the public service. Still the great mass of physicians plied their trade by ministering to the suffering of afflicted individuals.

Latterly, throughout the field of science there has

been a great interest in chemistry. The clearer understanding of certain physiologic and pathologic processes through chemical research, together with the remarkable advance in chemotherapy, has tended to put chemistry very much in the foreground, to the great good of individual sick persons, as well as to society at large. Likewise, through the development of anesthesia and asepsis the field of surgery has grown to a degree of perfection and usefulness beyond the dreams of the most enthusiastic but a few years ago. Let us hope, indeed we may expect, that medical scholarship, as exemplified in the schools, will continue to develop. Certainly the greater and greater participation by governmental departments in sanitary science and preventive medicine carries great promise, while specific therapy and surgery show no evidence of a slackening pace.

Yet man does not live in a vacuum. He has, as Cannon¹ has so ably pointed out, an internal and an external environment. He is a reacting organism continually played upon by environmental stimuli, and his social status has many important medical implications.

Slightly less than two hundred years ago, a wave of humanitarianism came upon Western civilization. Ruthless, predatory man paused for a moment in his egotistic career and cast a pitying glance at his less fortunate brother. He found a substantial component of human society utterly degraded, the depths of degradation being expressed by the jail, the poorhouse and the asylum. Strong hearts and courageous souls sought to alleviate the condition of these persons, and substantial progress was made through the improvement of public institutions. Very early there appeared an important medical component in this undertaking, and doctors were frequently found in positions

*The Annual Discourse delivered at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.
†Dean Tufts College Medical School, Chief, Nervous and Mental Clinic on the Peninsula.

of leadership in this field of human endeavor. At first expressed through better sanitation, more humane treatment and better care of the sick, this medical interest gradually became focused on

complete without a knowledge of the situation in which it was placed. Psychiatry has accordingly tended to some extent to be a bridge over which medicine has passed into the social sciences. Many

FIGURE 1.

A community of pines, showing a homogeneous appearance.

the personalities of the individuals and their behavior in society. From this lowly origin has developed the specialty of psychiatry, and we now think of many of these submerged persons in terms of mental disease, defect or peculiarity.

of the data of the social sciences were found to be quite sterile so far as their biologic content was concerned, but gradually there has developed in the fields of sociology, psychology and psychiatry a meeting point in the behavior of the individual,

FIGURE 2.

A closer view of the pine community, showing an inequality of growth.

The study of these patients by modern technics of physical examination reveals very little. Nor were the majority of their ills capable of attack by either specific therapy or surgery. It was soon found that a study of the organism was quite in-

and a concern over the situation in which he is placed.

If the problems of medicine are fundamentally biologic, it is important as a means of gaining perspective that the elementary principles of liv-

ing matter be known, and that natural law be kept continually in mind. It is perhaps well to begin our study with some simpler form of life. The pine tree may be taken as an example. If we view a community of pines from a distance, the whole group appears to be a homogeneous mass of verdure, but if we examine it more closely we find it to be made up of individual trees. The most superficial scrutiny shows a gross disproportion in the growth of these trees. Some appear to be sturdier and healthier than their comrades. Their growth has been greater, and they obviously get more sunlight from the air and water

or to Sorokin's¹ concept of a cycle of cultures is not important. Throughout Nature there is a tendency on the part of organisms to develop and grow. I take it that no one will dispute the contention that this principle applies to man as well as to pine trees. Yet, when we study the pine tree our attitude is relatively dispassionate and correspondingly less biased, whereas the study of man immediately involves the operation of factors not present when judging the rest of Nature. Among these factors are the ethical, humanitarian and moral. Nevertheless, this does not invalidate the principle of Darwin's law of the survival of

FIGURE 3.

A crowd of people, showing homogeneity.

from the ground than their less fortunate fellows. The stronger ones grow to the hurt and even to the death of surrounding trees. Yet we do not express this greater growth in teleological terminology, or impute hostile motives to the more successful tree. We speak of the survival of the fittest, but do not imply a conscious attempt to destroy one another. This condition can better be expressed in functional terms, as follows: There is a propensity on the part of all trees to grow, and it is a function of certain elements in the trees to get all the sun and water that they can. As a result of the carrying out of this function, growth takes place. The better endowed trees prosper disproportionately. The effect on the other trees is secondary and incidental. Whether we subscribe to Darwin's² evolutionary theory of a constant betterment in nature, to Spengler's³ theory of a rhythmic rise and fall for better or worse

the fittest. It is natural for man to grow. There are elements in his make-up that function to get the wherewithal by which growth takes place. The hurt, if any, to other elements in society is secondary and incidental. The growth of certain persons is bound to be greater than that of others. However this may be, it is a fact that the operation of natural law is as if the conduct of the individual in relation to others were purposeful. The selfish and predatory man operates in society as if he were determined to dominate his fellows, and, in certain cases, to destroy them. For this reason, social engineers must take cognizance of the hurt, if any, done to society by the unrestrained operation of natural propensities in superior individuals. Likewise, it must take cognizance of the frailty, folly and incapacity of others who, though not purposely trying to destroy themselves, act as if such were their purpose.

One fundamental difference between the pine tree and the human being is the effect of growth by the individual on its fellows. With the pine tree, although the community may offer more or less mutual aid through soil conditioning, protection from hurricanes and otherwise, this is not so pronounced as in the human being. Ordinarily, where the human being grows to great stature he provides opportunities for similar, even though less extensive, growth on the part of many asso-

referee our mutual relations, the latter is the field in which it should operate, always being careful not to apply the police technics used to curb exploit for the purpose of interfering with real service. Whether or not the employment of one person by another is service or exploit is a delicate question. Attempts have been made to define it on the basis of wages and hours of work. In actual practice this may have very little to do with determining the distinction. Employment of a handi-

FIGURE 4.

A closer view, showing individual differences.

ciates. In fact, the less capable people are often quite dependent for their status on the initiative, energy and creative genius of those who are superior. When this is done with candor, good faith and fairness, the superior persons may be said to be performing a service to their less well-endowed associates. On the other hand, there is a line beyond which this becomes a disservice and is called exploit. Veblen⁵ designates the means of exploit as force and fraud. If we accept this definition, any use of another's talents that embodies force or fraud is exploit and may be considered a disservice. Obviously, if the government essays to

capped person at a low wage may be a great service to both the individual and the community.

If this same type of scrutiny is applied to society, in the mass, human beings appear to be very much the same. Their basic physiologic striving is identical, and we often speak of society as if it were a homogeneous mass of identical individuals. Here again closer scrutiny shows a stratification. By whatever standard we measure individuals, whether political, economic or social, each falls in a rather definite place in a great social hierarchy. According to Sorokin⁶ this is true of every society that has been the object of scrutiny.

Leveling processes have been tried from time to time, but have always ended in disaster. Sorokin speaks of the social structure as a cone, the profile of which, although it fluctuates somewhat from time to time, tends to be the same. During good times, the rich grow richer, but every element of the cone shows a similar benefit. The general character of the cone remains about the same.

Again, if we scrutinize this social mass we note a constant mobility. That is, we find a tendency on the part of certain organisms to grow out of proportion to certain other elements and to rise to a higher and higher level. Certain other elements either remain stationary or tend to settle out, forming a vast sediment of relative immobility

FIGURE 5.

This Cone of Life shows the relatively greater numbers in the lower registers, and the general mobility of the mass of the cone, with a settling out of the more seriously handicapped into the lower strata.

at the lower levels. To be sure, certain persons, through the wisdom of trustees, are able to remain more or less immobile in the upper strata for a while, but a constant tendency is found to revert ultimately to lower levels.

Much might be said concerning the factors making for growth. A superficial study of those elements tending to rise seems to indicate the presence of such attributes as strength, intelligence, industry and virtue. Perhaps the generation of energy on the part of the individual is of first importance. If we break down the behavior of the individual into its elementary dynamics we find first a striving on the physiologic level. This has to do with the basic and more or less automatic factors in life. These are carried out quite unconsciously and, of course, are purely selfish. To a lesser extent, human behavior is conditioned by social pressure. Such factors as morality, prudence and

cautiousness tend to be in this social category, and, therefore, are to quite an extent dependent on indoctrination. Lastly, a greater or less amount of intellectual guidance tends to modify and direct the operation of the two former forces. Here again, people differ in the basic physiologic drives im-

FIGURE 6.

The driving forces behind human behavior are the automatic or physiologic instincts varying with individuals; the sociologic component is that part of human behavior which responds to social pressure and hence is subject to indoctrination, and last, if not least, is the intellectual force.

pulling them forward. They also differ in their responsiveness to social pressure, and, lastly, they vary tremendously in intellectual equipment.

There is still much work to be done in understanding the factors of social mobility, but it is possible to study the composition of the relatively immobile sedimentary elements in society because such persons tend to come under public scrutiny, and their misfortunes become matters of public record. A gross-specimen view seems to indicate an almost pure culture of social disease at the base of the social cone. They have been classified by state departments and institutions through the administrative officers of society as the sick, the poor and the bad. It is true that we find sickness, poverty and crime throughout the whole of society. The sediment differs largely in that it is quite a pure culture of these evidences of social sickness. If we examine these categories a little closer we find a marked degree of overlapping among them. The sick are often impoverished,¹⁻³ the poor are often bad, and vice versa. I have been told that 68 per cent of the people admitted to a large poorhouse had previously been in jail. Large percentages of criminals are known to have ill health, and the whole realm of disease is often closely related to the other disabilities.

Until recently a large municipal hospital would not accept cases of venereal disease to its wards. So that all we can say of these three groups is that certain individuals are preponderantly sick, and, therefore, their illness is what calls for first attention. The others are preponderantly poor or bad. In the field of etiology, their difficulties

FIGURE 7.

This diagram shows the chronologic application of the forces indicated in Figure 6. The physiologic instinct is more overwhelming in childhood, and the problem of training young children has largely to do with conditioning physiologic responses. The later period of school is the time for indoctrination and the application of social pressures. A period of chaos is indicated during the turmoil of adolescence. Lastly, during adult life the intellect is supposed to take over more or less direction of these earlier basic factors.

appear to spring from the same sources. They all tend to be handicapped, each one with a large medical component. Therefore, it seems axiomatic that medicine cannot serve with maximum social benefit without taking cognizance of these matters. Furthermore, the terms sick, poor and bad are all relative. We can represent their degree as with a thermometer. At the top it is generally recognized as hot, at the bottom as cold, and yet the exact position where cold ceases and hot begins is relative. If one goes from a room with a temperature of twenty into a room at fifty, he says it is warm. Yet if he had previously been in a room with a temperature of seventy, it would seem cold. Likewise, there is no level at which one may be said to be good or bad, rich or poor, well or sick. For this reason it would seem fallacious to be too arbitrary in setting standards. A person with psoriasis may be said to have a chronic, incurable disease, yet he may suffer very little disability from it. Similar observations might be made concerning the poor and the bad.

The number of dependents in a community is

a variable that fluctuates between certain levels. Under natural law, during prosperous times, all stratum of society are benefited, even the insane. Likewise, during bad times all suffer. Those at the upper levels, of course, have more fat on which to live, and, therefore, suffer less in the essential matters. Bad times usually lead to remedial efforts on the part of society to alleviate the suffering of those whose situation is most desperate. Although in theory, the roof of the relief load is governed by the necessities of the individual, in practice, dependency is artificially expanded. The tendency to exploit is not peculiar to any class of people, but is a component of every person. Normally, during hard times, social necessity creates a pressure, which induces the less well endowed to work harder at longer hours and lower wages. It may be well for government acting as a referee to see to it that such persons are not exploited by their stronger fellows. How-

FIGURE 8.

Heat and cold are variables, and there is no point where one can arbitrarily divide temperature sense into hot or cold. Likewise, health and economic and moral statuses are variables for which it is difficult or impossible to set arbitrary standards.

ever, if such attempts, carried out horizontally, are too beneficent, there is apparently no limit to the rising height of the relief load. When the relief load becomes large enough, it too becomes the object of exploit by politicians, social workers and government officials. The politician exploits the distress of these people for purposes of votes, the social worker and government official because the size of their jobs tends to enhance their prestige as well as to increase their salaries. Incidentally, the same factor of growth enters this situation if those having charge of dependent groups happen to be successful promoters, and the growth of the individual and of the problem takes place

hermore, there is some ground
futile to set an arbitrary stand-
ard, the use of the word "stand-

There can be an average
but there can be no standard arbi-

because of individual differences. What

gives a pittance to one man is like a fortune to
another. There has recently appeared a discus-
sion of this problem in which it was stated that 66
per cent of the population were living on a sub-
standard basis.¹⁰ This is like saying that the aver-
age is below the average. It may be a mistaken
kindness on the part of those in the upper level
to set the satisfactory level of living at a point
higher than that at which 66 per cent of the peo-
ple can sustain themselves. Furthermore, this im-
mediately provokes the question: Can a minority
of the people sustain a majority at a level of living
higher than they are able and willing to sustain
themselves? If the answer to this question is, Yes,
another question is immediately provoked: How
small a minority of the people can sustain how

THE CHILD

The child is a relatively helpless person. Where-
ever evidence of social disease is found, there is
always an excess of children. The law does not
recognize the child as legally competent until he
is twenty-one years old. He cannot vote, hold
title to real estate, inherit property, incur debts
or marry. Thus, we have the traditional depend-
ence and incapacity of the child, and among the
first efforts in the field of social welfare were
attempts to protect children.

Population studies¹¹ estimate about 35 per cent
of the inhabitants of Massachusetts as under twen-
ty-one years of age. This would place the num-
ber at approximately one and a half million.
General health measures appear to be fairly well
organized, and tremendous strides have been made
in control of infectious disease. However, there
are social responsibilities that it is imperative to
recognize in connection with children. Some have
competent but many have incompetent parents.
The doctor certainly has responsibility in this
field. In the first place, he brings the child into
the world. He treats the various ills to which chil-
dren are peculiarly susceptible, and, in matters
of nutrition and growth, he takes the initiative
and leadership, frequently being obliged to hold
parents to their task. In the field of immuniza-
tion the individual doctor has not taken so much
initiative as might be desired. Who could better
participate in the education and training of the
child than the one who has had so much to do
with the other phases of his upbringing? There
is a tendency on the part of parents to make pets
of their children, and to be lax in the discipli-
nary requirements of their training. The devel-
opment of inferiority and paranoid reactions may
well be the result of parental bias and leads to
unhealthy attitudes of mind.¹² Thom¹³ has many
times shown the relation between faulty habits
in young children and later maladaptations. So
much has been said concerning this matter that
it hardly seems necessary to reiterate. Further-
more, from time immemorial the minds of young
people have been prepared for the struggles and
vicissitudes of adult life by the promulgation of
certain attitudes. The competitive elements in
school marks, organized play and other attain-
ments may be used in such a way as to be very
helpful, or they may be exploited to the injury
of growing children. The doctor should not as-
sume these tasks alone, but should do his share
along with parents, religionists and teachers.¹⁴ For-
tunately, the majority of children are only tem-
porarily incapacitated, for, with the development

TABLE 1 *Groups of Handicapped People in Massachusetts*

CLASSIFICATION	NO. OF PERSONS
Population of Massachusetts (1940)	4,316,211
Aided by private charity	1,743,863
Aided by State and towns	631,556
Aided by Boston Community Chest (1940)	400,000
Employed by WPA	82,000
Arrests (1939)	209,343
Admitted to penal institutions (1938)	15,000
Under care of Veterans Bureau (1940)	1,104
Under care of Department of Mental Health (1940)	26,000
Estimated incidence of feeble-mindedness (2 per cent)	86,000
Estimated incidence of chronic disease	500,000
Estimated incidence of physical defects (3.1 per cent)	124,000
Admitted to hospitals (1940)	424,551

large a majority at a level higher than they are
willing and able to sustain themselves? To be
sure, this seems simple enough to the levelers
through the field of taxation. However, in the
imperfect state of the human mind at the present
time, it appears that there is a point in taxation
for the purpose of assisting the less well endowed
at which the better endowed is discouraged or, at
any rate, deterred and inhibited in his capacity
to grow, thus invoking the law of diminishing
returns. Society cannot lift itself by the boot-
straps any more than the individual can.

To present more specifically the problem of med-
icine concerning these matters, it seems appro-
priate to break the groups down further and set
them up in new categories as follows: the child,
the aged, handicapped classes, the insane, the
feeble-minded, the neurotic, the disordered person-
alities, drug and alcohol addicts, and the physically
diseased.

of maturity, they soon emerge from the sedimentary stratum and take their place at whatever level in the social scale their capacity to grow places them.

THE AGED

At the end of the scale we have the aged. Much has been written and said concerning the ever-increasing number of the aged. It is estimated that at the present time about 8 per cent of the population is over sixty years of age.¹² This gives a population of approximately 350,000 old people in Massachusetts. We do not know how many of these are dependent or what they are doing. Some 80,000 are receiving old-age assistance, and the number is increasing each year. Many new bills are before the Legislature to lower the age of eligibility and to increase the amount paid to each person. Much that has been said concerning the situation of the child might apply with equal appropriateness to the aged. Likewise, conditions make it increasingly difficult for the aged to support themselves in ordinary competition with young, vigorous persons. They are more susceptible to illness, probably more prone to accident, and in many ways a greater liability than younger people. The grant of a special form of relief to the aged has tended to weaken the pressure on children to care for their parents, and has likewise reduced the incentive on the part of the older persons to carry on. Innumerable private institutions have grown up depending on the helplessness of these aged persons for their support. They are also particularly vulnerable to exploit.

Medicine must shoulder its share of the responsibility for the care of this group, and should furnish leadership in the field of social engineering as applied to the aged. Obviously, if they were all pensioned, the cost would be almost prohibitive. It also seems true that the vast majority of older persons would be happier pursuing some gainful occupation, and maintaining thereby their self-respect and dignity. There is a great disproportion between chronologic and physiologic age about which more should be known. Certainly a program for aged persons, preventing the indignities and deprivations of neglect, guarding against exploitation, and yet giving them an opportunity for a full, satisfying life commensurate with their abilities, needs the medical profession badly. The beginning of a specialty of geriatrics augurs well for the future.¹⁵ When an aged person is found in the sedimentary zone of society he is usually there for good, and most of the aged grow increasingly unable to support themselves at levels above dependency.

HANDICAPPED CLASSES

There are many groups in our society against whom great odds are arrayed.

Approximately half the population of Massachusetts is female. Ordinarily, but 25 per cent pursue gainful occupations.¹⁶ They are susceptible to certain disabilities not common to males. When they work they receive a smaller salary, and are still quite dependent on male initiative to keep their status in society. For this reason, the capacity of the female to grow is limited as compared with the male, and they are therefore found in certain dependent positions out of proportion to their occurrence in society. This has been recognized by the provision for mothers' aid.

More than half the population of Massachusetts are foreign born. Coming to our shores from a foreign land has been a great stimulus to certain persons. By hard work, long hours and low wages they have advanced their status till at the present moment our colleges are literally overflowing with the children of immigrants. Alas, so are our prisons.¹⁷ Here again, competition is not even. The foreign born tend to receive lower wages than the American born and have less education. They are found out of proportion to their incidence in society in prisons, hospitals and poorhouses. An equal degree of success by a foreign-born person means greater ability, strength or industry. When they fail, they lack the resources to carry on and are consequently found in a sedimentary nonmobile stratum in excess to native born.

The Negro, largely by virtue of the amount of pigment in his skin, is a handicapped person in our state. When 25.9 per cent of the native white population of Massachusetts were unemployed, 33.9 per cent of the Negroes were out of work.¹⁸ They are found in hospitals and other institutions out of proportion to their incidence in society. Of a certain class of criminals admitted to the Charlestown State Prison, 10 per cent are colored, whereas their incidence in the general population of the state is but slightly over 1 per cent.¹⁹ This tends to place them at a lower level in society, to concentrate them in squalid districts, and thus increases their susceptibility to poverty, disease and vice.²⁰

Good social engineering on the part of the medical profession cannot equalize the opportunity for all, but it can recognize the situation and do its part toward a rational program for prevention and cure.

THE INSANE

Nobody knows how many insane there are. The only figures we have are state hospital admissions, but there is ample evidence of the wide distribution of mental disease throughout all strata of society. Those of us who are practicing psychiatry in the city, and attending large clinics, are in daily contact with a considerable number of persons with definite mental disease, yet of such a nature that their families are able to care for them. This applies particularly to the aged and to persons with mild depressive psychoses. Many of the inmates of nursing homes and sanatoriums are technically insane, although not carried on the books as such.

In the early days of our state hospital system, a hope was set forth that, if persons with mental disease could be brought in earlier and would stay longer, as high as 84 per cent of them could be cured.²¹ Upon this hope, to some extent, the state hospital system has developed until we now have approximately 30,000 under care in Massachusetts. Some have recoverable diseases, and their ultimate discharge can be predicted at the time of admission, but with the vast majority we are dealing with deteriorating processes, and they are looked on largely as problems for custodial care. Once the burden has been lifted, the family is very loath to assume it again. The only limit to the state hospital load up to the present time is the number of beds available.

This problem first of all calls for investigation. Already there appears to be some diminution in the number of persons developing mental disease because of syphilis, but this barely touches the surface. The state hospital system has already been expanded to a point where great resistance toward its further extension is met from tax-minded people. It has been suggested that a considerable number of inmates at present in state hospitals could be cared for in the community under proper supervision.²² For a number of years people have been encouraged, and almost exhorted, to send patients to hospitals for mental disease early. Perhaps we are reaching a stage where some selection must be made, and the medical profession must equip itself to supervise intelligently large numbers of persons with mental disease in the homes of the community. It is obvious that the vast majority of persons with frank mental disease are thoroughly disabled and bound to be in the sedimentary stratum of society.

THE FEEBLEMINDED

Certain children do not develop intellectually and are called feeble-minded. There may be some

debate as to exactly the level of intelligence that should stamp one as feeble-minded, but the helplessness of this group is universally recognized. Conservative estimates place the number of feeble-minded in Massachusetts at around 2 per cent. If this is true, there are at least 86,000 feeble-minded in Massachusetts. Approximately 5000 of these are in institutions for the feeble-minded. One hundred years ago, a beginning was made toward training the feeble-minded, the idea being that with special training they would develop and take their place as normal citizens. Unfortunately, this fond hope has not been realized. The number in the institutions, as set forth in a recent study,²³ indicates an ever increasing age and a diminished discharge rate. At the present time 57 per cent of the population of the schools are over twenty years of age, that is, beyond the age at which education is usually successful even in healthy persons. This report, which is the latest statement concerning the problem of the feeble-minded in Massachusetts, makes no attempt to solve it but ends with a fervent plea for one more institution. If the proponents of this measure should be successful, the total result would be that instead of their being 81,000 feeble-minded abroad in the community, there would be 79,000. This does not seem a sufficient end. Here is a challenge to the medical profession. At the present moment, we have little to offer between 100 per cent incarceration in a school for the feeble-minded and 100 per cent neglect in the community.

Although the general helplessness of the feeble-minded is recognized, they are held up to many responsibilities. They are entitled to vote and to buy liquor, and are called on to support themselves. The average doctor pays little attention to this group. There are some whose parents are thoroughly competent and able to protect and provide for them, but the vast majority are turned loose and do much to augment our social perplexities. The number of feeble-minded in jails, poorhouses and hospitals is proportionately large. When the physician is consulted, he shakes his head, speaks vaguely of the state schools and their overcrowding, and often has little more to offer.

Now there is a level at which many of the feeble-minded can lead independent lives.^{24, 25} In fact, of all those discharged from the state schools 15 per cent are considered capable of self support, and 14 per cent are capable of partial self support. Perhaps, the group sent to the school tend to be the more troublesome cases.

Certain developments in society during the past few years have made it increasingly difficult for

handicapped persons to pursue gainful occupations. These militate particularly against the feeble-minded, and may therefore be discussed here. In the first place, the change from an agrarian and rural to an urban community presents problems. Eighty-nine per cent of the population of Massachusetts now dwells in cities. The transition from large, independent households to tenement dwellers makes it increasingly difficult for a family to develop the talents of a feeble-minded person, and especially, the field for productive labor on the family farm is well-nigh closed. Likewise, the control of certain people by workers' organizations tends to exclude the feeble-minded and other handicapped persons. Again, the setting of a minimum wage tends to exclude those who are not competent to earn that wage.

To raise the standard of living of certain of the lower strata of society, ignoring the element of handicap among such persons, minimum-wage laws have been set up. It has been perhaps rather naïvely hypothesized that if a minimum wage was set in an industry the lower elements in society would be more or less automatically introduced to a higher scale of living. I have been unable to procure extensive data on this matter, which would seem to be elementary, and yet there is some reason to suppose that the setting of a minimum wage automatically discharges those persons who are not competent to earn this wage, thereby lowering their scale of living—in fact, reducing them to a welfare level, the jobs at higher wages being taken by persons coming in from horizontal positions who are capable of earning this wage. This is an example of an attempt to solve a social problem on theoretical grounds without adequate preliminary research. Lastly, the carrying of insurance against industrial accidents has led to a medical examination of applicants for jobs, and thereby tends to exclude any who may be considered accident prone. All these things have limited the fields of endeavor open to handicapped persons, especially the feeble-minded.

The medical profession should furnish leadership in providing for the approximate 80,000 non-institutionalized feeble-minded. Obviously, it is futile to think of institutional care for this vast throng for the reasons given above. The feeble-minded tend to constitute a substantial part of the immobile elements in society, remaining a more or less permanent part of the sedimentary stratum and furnishing more than their share of disease, poverty and crime.

THE NEUROTIC

Wherever large numbers of sick persons are found, there is an enormous amount of functional nervous disease. Estimates in large clinics, and in general practice, have run as high as 35 per cent.²⁶ This group is ill-defined. Gradually medicine has come to look on their trouble as in the emotional field, yet they run the gamut of clinics, have many operations, and are a very great load on organized medicine. If wealthy, they are received enthusiastically by the practicing physician, but they are looked on with consternation in the free clinics. Their difficulty is perhaps situational to some extent, and many of them appear to be mixed medical and social problems. Welfare lists contain the names of many persons who at one moment are considered malingerers, and another as afflicted with some physical disease. Although many psychologic and physiologic studies have been made on this group in the last few years, there are still inadequate data as to the natural history of such illnesses, and we are still lacking a good statement as to their place in the whole medical scheme of things. These illnesses tend to be chronic and disabling, and therefore frequently place their victims in the dependent group.

THE DISORDERED PERSONALITIES

This group occupies a vague zone in the social hierarchy and is still ill-defined by the medical profession. It has to do with those persons who, through personal peculiarities, are unable to adjust and adapt themselves to the requirements of society, and so become social problems in one way or another. The morbidly contentious find it difficult to obtain employment. They are continually agitating, and nobody wants them. They are frequently found on relief, in prisons and even in hospitals for the insane. The inadequate personality often gives up without a struggle and is feebly resistant to alcohol, and the emotionally unstable are often incapable of sustained productive effort. This group not only forms an important component in definite social disorders, but makes up a large number of those who are found in clinics appearing on the surface as neurotic. Needless to say, many of these persons appear in the sedimentary stratum.

Psychiatrists have expressed a belief that if these individuals were properly handled as children much of their difficulty in adult life might be avoided. Whether this is true, experience alone can tell. Nevertheless, it is true that the under-

standing physician who has an attitude of detachment is a great help in handling such cases. There is a place for each one of these people in society, if such a place can be found, but without skilled advice and understanding, they form one of the most turbulent and distressing factions with which we have to deal. There is no estimate of their number except to say that it is very large. One study set the percentage of the inmates of a large prison to be classified as personality disorders as very high.

DRUG AND ALCOHOL ADDICTION

Addiction to habit-forming drugs, including alcohol, has long been considered a medical problem, and, in the past, there have been many programs under medical stimulus and leadership attempting to attack this problem in an intelligent way. We have no census of alcoholic patients, but every index tends to show the load to be tremendous. There are approximately 84,863 arrests in Massachusetts every year for drunkenness.¹⁷ Thirty-two per cent of the patients admitted to the state hospitals are said to be intemperate.²⁷ Alcoholism has been shown to be a very large component in the admissions to the Boston City Hospital.²⁸

There is no more discouraging problem with which to deal than that of alcoholism. The police handle the same cases over and over again. Certain persons have literally hundreds of sentences to jails and houses of correction. At the present moment, although there has been very recently a vigorous attempt to promote attention to this group, there is no state-wide program for prevention or cure, nor is there an adequate meeting of the minds of police, welfare and medical authorities. Quite a bit of the beneficent effort to raise the level of living of certain of the dependent groups is almost entirely vitiated through diversion of relief from the home to the saloon.

The drug problem is similar, but, of course, very much less flagrant. A surprising number of those who fail to meet their obligations in life are alcoholic and get into the sedimentary immobile stratum of society.

THE PHYSICALLY DISEASED

I shall not attempt a wide discussion of the social problems of the physically ill, since much has been written on this subject of late. There are many data to indicate a greater incidence of disease among persons in the low-income groups. There has been a suggestion from some sources that ill health is due to inadequate medical care. This is a glorious tribute to the efficacy of medical

practice, but has little basis in fact. It is well known that much of the reduction in disease has been due to sanitary measures, and that a relatively small amount has been due to curative medicine. Sanitation is almost entirely, at the present time, in the hands of the government, and the work of the practicing physician is largely in the field of curative medicine. However, there is a social component in the realm of physical disease that offers adventure in a somewhat new field.

It is estimated that 39 per cent of the population have some form of chronic disease that is disabling.^{29, 30} Likewise, it is estimated that 3.1 per cent of the population are crippled to a point of being disabled.³¹ Then, the blind and the deaf should be added to this total. As with the others, modern social trends have militated against the possibility that these individuals will sustain themselves, and it has tended to make the problem social as well as medical. The well-known tendency of certain persons with minor disabilities to exploit their illness as a means of gain should be noted. The rehabilitation of disabled persons, the organization of co-operative workshops where they may pursue some sort of gainful occupation, and the breaking down of prejudice, as well as the keeping up of the morale of handicapped persons, need medical participation.

One important group is that of the epileptic. It is estimated that 0.17 per cent of the population have occasional convulsions. Recent developments have shown that a large number of epileptics can be kept symptom-free under medication. The others find it difficult to sustain themselves and need great ingenuity in planning special programs.

The attitude of different persons toward disease is a well-known variable. One person losing a phalanx on the fifth finger tends to exploit this disability and retire from active duty, whereas another person puts off until too long, cutting down on vigorous effort.

* * *

From the above it would appear that throughout Nature there is a tendency on the part of individuals to form themselves into a social hierarchy according to their capacity. Likewise, there is a level at which survival is precarious. In human society, the destruction of the less capable is prevented by the efforts of the more capable. The least capable are handicapped by sickness, poverty and vice, and it is the task of organized society to care for them.

This is, in the main, a clinical problem calling for the use of the scientific method, that is, the method of diagnosis as a preliminary step to

treatment. There are extensive and intensive methods by which the problem can be attacked, analogous to sanitation and salvage in medicine. The medical profession has great opportunities as well as obligations in dealing with these matters since a professional personnel trained in scientific methods is available, and since, because of overlapping between these groups, it is inevitable that physicians participate in the solution of these problems.

OBSERVATIONS AND SUGGESTIONS CONCERNING NEUROPSYCHIATRIC EXAMINATIONS FOR THE ARMY OF THE UNITED STATES*

THEODORE J. C. VON STORCH, M.D.,† GEORGE O. PRATT, M.D.,‡ MALCOLM J. FARRELL, M.D.,§
DONALD E. CURRIER, M.D.,|| AND HENRY R. VIETS, M.D.||

BOSTON

SINCE August 27, 1940, a modified state of national emergency has existed in the United States.¹ Under the circumstances, it has become necessary for large numbers of young men to enter the Army of the United States. All candidates for the Army are subjected to various examinations to eliminate those who are unfit for military service. One of the most important of the examinations is the neuropsychiatric evaluation of the candidate.

||Lieutenant Colonel, Medical Corps; chief, Medical Division of Selective Service, Massachusetts.

||Major, Medical Corps, retired; associate in neurology, Harvard Medical School.

A review of the neuropsychiatric problems during World War I may suggest the magnitude of the present problem.²⁻⁶ In 1916, just before the entry of this country into the war, one tenth of all discharges from the Regular Army were for neuropsychiatric disorders. This discharge rate was three times that of the hospital admission rate of the adult population of New York State for the same disorders.³ In 1917 and 1918, 3,500,000 soldiers who had been passed by local examining boards and admitted to the Army subsequently underwent special examination. Almost 2 per cent (69,394) of these men were found to be suffering from neuropsychiatric disabilities.⁴ What is more significant is that 96 per cent of these disabilities were considered to have arisen *not* in the line of duty. Available data on 50,000 of these men revealed that 85 per cent began their neuropsychiatric disorder at least five years before entering federal service. Forty per cent (27,000) were detected during preliminary physical examinations in the Army after having been

passed by their local examining boards. Thirty-two per cent (22,000) were revealed by consultation with medical officers of their units, and 24 per cent (16,000) were discovered by their commanding officers. Unfortunately, many officers were commissioned who later proved to have nervous and mental defects. The total 69,394 cases were divided as follows: mental deficiency, 31 per cent; neurosis, 17 per cent; psychosis, 11 per cent; nervous disease and injury, 10 per cent; epilepsy, 9 per cent; "constitutional psychopathic inferiority," 9 per cent; endocrinopathy, 7 per cent; drug and alcohol addiction, 6 per cent.⁴ During the war, all groups constituted a major problem. After the war, psychoses became the major problem. In March, 1921, 70 per cent of all neuropsychiatric cases under observation were psychoses. By 1927 almost 50 per cent of all patients receiving hospital treatment as beneficiaries of the United States Veterans Bureau were neuropsychiatric cases.⁵ It has been estimated that each such case has cost approximately \$30,000 to date.

These are the conditions resulting from the examinations of 1917 and 1918. Since then an appreciation of neuropsychiatric principles and practice has become more widespread in military circles. Unfortunately, the rigors of warfare have increased with advancing knowledge. Military service today demands more emotional stability and intellectual activity than ever before. The coordination of the soldier is of vital importance in these days of carefully synchronized mechanical operations. Equally important is his ability to act intelligently and with initiative in small independent units. Therefore, the demands on the neuropsychiatrist have increased proportionately.

The duty of the neuropsychiatric examiner is multiple. First, he must eliminate those who, because of demonstrable organic or less clearly defined functional abnormalities of the nervous system, are unable to perform their appointed tasks. Secondly, he should ascertain whether the candidate is vocationally fit for the duties of a modern soldier. Finally, he is asked to consider whether the candidate will remain useful during his ten years' reserve duty following the initial training period. This is no simple task. Careful scrutiny of each candidate is required. At least one hour is necessary to perform a reasonably adequate personality estimate. The present emergency demands examination of large numbers of men. Hence, it is impossible to maintain the usual standards of neuropsychiatric examination. Because of the present emergency a compromise must be made.

When it is realized that the general practitioner of the local selective-service board is allotted approximately thirty minutes for a complete examination and the specialist on the induction board from five to ten minutes for neuropsychiatric evaluation, the task seems insurmountable; fortunately, it is not. A reasonable compromise may be reached between perfection and failure to fulfill the purpose of the examination. Bearing in mind the existence of a national emergency and the present organization of the mobilization system, the results obtained under these circumstances have suggested methods whereby such a compromise can be reached. It is the purpose of this article to present observations and suggestions derived therefrom, based on the examination of 5550 candidates from the Fourth Recruiting District (Boston Area). These included 4393 selective-service candidates, 750 National Guardsmen and 407 recruits for the Regular Army.

Under the present system of mobilization there are three channels through which the Army is rapidly increasing its man power (Fig. 1). The first is by means of enlistment in the Regular Army. Except for potential pilots in the air force, medical specialists are not routinely employed for the examination of candidates before induction into the Regular Army. Enlisted recruits are examined by officers of the Army Medical Corps. There is no examination by a neuropsychiatrist. Examination of recruits for the Regular Army has not revealed a significant proportion of neuropsychiatric disorders. Within the last six months, one of us (G. O. P.), together with two other officers of the Army Medical Corps, examined, among others, a group of 407 recruits from the Boston Area. None of the examining officers had received special instruction in neuropsychiatry. They rejected 0.7 per cent of the recruits for neuropsychiatric disabilities. Three months later 405 volunteers were examined by the neuropsychiatrists of the Boston Area Induction Board. The rejection rate for neuropsychiatric disorders in this group was 3.2 per cent. The two classes of volunteers were in the same age, racial, social and geographic groups. They differed in that the men in the second class had been pronounced normal in all respects by the examiners of the local boards whereas those in the first were entirely unselected. It is to be expected that fewer neuropsychiatric disorders would be present in the latter (selected) group of candidates. Nevertheless, trained neuropsychiatrists discovered approximately five times as many neuropsychiatric disorders. Similar examination of applicants for the Regular Army by

trained neuropsychiatrists might uncover neuro-pathic or psychopathic traits in many of the applicants who are now accepted for service.

The second channel of entry into the Army is by induction of National Guard units. National guardsmen have received a general physical ex-

may be specialists. During recent inductions of National Guard units an appreciable amount of disability was discovered by the medical induction boards. One such board inducing Massachusetts units was composed of nine examining officers, one of whom happened to be a neuro-

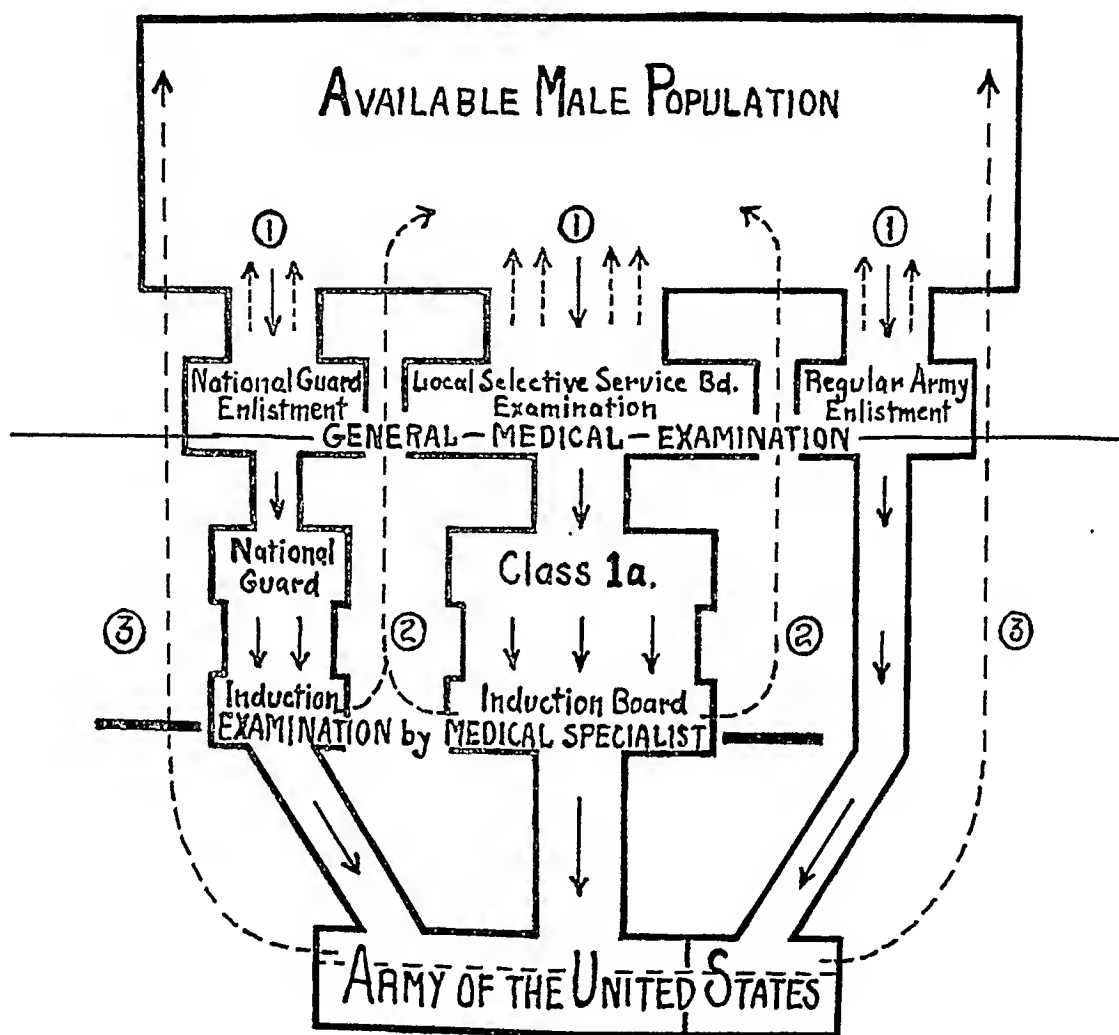

FIGURE 1. Channels of Entry into the Army of the United States.

- (1) Selection of candidates by means of general medical examination by local practitioners.
- (2) Further selection of candidates through induction-board examinations by medical specialists, including examination by neuropsychiatrist.
- (3) Further examination and rejection, if necessary, without benefit of governmental care and treatment, for neuropsychiatric disabilities incurred before entrance into the Army or within the first six months after entrance.¹⁰

Members of the Regular Army constitute a separate unit within but not a part of the Army of the United States.

amination before admission into their units. Here again, medical specialists are not routinely employed for the detection of disabilities. On the other hand, the men have been subject to scrutiny by their officers during their training periods. This constitutes an additional opportunity for detecting gross disabilities. Finally, before induction into the Army, the guardsmen are subjected to examination by a medical board some of whose members

psychiatrist (M. J. F.). The latter interviewed approximately 750 men in seven days, or slightly over 100 men per day. Although an experienced and qualified neuropsychiatrist, he was able to make no more than a cursory evaluation of each candidate. Even under these conditions a percentage of 0.8 of rejectable neuropsychiatric disabilities was uncovered. Thus a single experienced specialist was able to discover the same

amount of neuropsychiatric disorders in a group of previously examined men as had been uncovered by three general practitioners in an unselected group (Regular Army recruits). It is probable that more careful examination of the National Guard group might have revealed additional disabilities.

The third and largest portal of entry into the Army is through the Selective Service Act of September 16, 1940. A man who is called for service is subject to the following routine: investigation of social and occupational status; call for examination according to his order number; general physical examination by the medical examiner of the local selective service board; reference of the candidate to a medical advisory board for consultation in doubtful cases; examination by an induction board of medical specialists if the candidate is placed in Class 1-A by the local board, acceptance or rejection by the induction board for general active military service, if the candidate is rejected, return to the local board for reclassification or for re-examination by a medical advisory board; possible return to the induction board if placed in Class 1-A by the advisory board.

There are approximately 6400 local selective-service boards in the United States. There are 173 in Massachusetts. The medical examinations for these boards are performed by local general practitioners, surgeons or internists as a gratuitous, voluntary service. The presence of specialists on such boards is unusual. By March 1, 1941, 457 physicians had been appointed to these boards in Massachusetts. There are from one to five examiners on each board. Each physician examines from three to five men per day when on duty with the board. The number examined varies with the quota of the board in question. Since most of this work must be done in addition to his usual practice, the examiner expends about thirty minutes per candidate. During this time a complete physical examination and personality estimate of the candidate are expected from the examiner. In the neuropsychiatric field especially, this is no trivial task. Judging by the rejection rates maintained by the majority of the local selective service boards in Massachusetts the local examiners are performing an excellent service to the nation. If there is any criticism, it is that additional stress might be placed on the neuropsychiatric aspects of these initial examinations.

The general practitioner on the local board possesses certain advantages over the specialists of the induction boards. The local examiner has more time with each candidate. The alert physi-

cian may learn a great deal about a candidate's personality and background in a half hour interview. Social agencies may be called on to investigate home, school, court, welfare and hospital records, when necessary. Consultations from a medical advisory board are available in doubtful cases. By utilizing their advantages the examiners on local boards are in a position to save both the Government and the candidate a great deal of time, effort, confusion, expense and disappointment.

Medical examination by the local boards is intended to exclude all those who are unfit for general active military service. The criteria for such exclusion are listed in the Mobilization Regulations (M R 19) of August 31, 1940. An analysis of the rejection rates from 124 of the 173 local boards in Massachusetts has shown that from 30 to 87 per cent of the candidates have been rejected for various defects. The average rejection rate is 58.5 per cent. It is estimated that about 9 per cent of the candidates were rejected because of neuropsychiatric disorders.

Medical advisory boards have been organized as a consultation service for the local boards. There is approximately one medical advisory board for every ten local boards, or about 640 in the United States. There are 15 such boards in Massachusetts. The medical advisory boards are composed of a group of outstanding specialists in the community. Their services are offered for consultation on request by the chairmen or examiners of the local boards. Not many men are examined by the neuropsychiatric consultants. Therefore, they are often able to spend several hours or more evaluating the doubtful cases. Electroencephalography, lumbar puncture and other laboratory techniques may be employed by these boards when indicated. Expert neuropsychiatric consultations are made available by these boards. It is probable that, if more such consultations were requested, fewer candidates would be rejected by the induction boards.

The medical induction boards are the final barrier before actual entrance into the Army. There are three such boards in Massachusetts. These are composed of specialists who re-examine all candidates placed in Class 1-A by the local medical examiners. The Boston Area Induction Board, with which this report is primarily concerned, has been active since November 18, 1940. It is composed of a medical director from the Army Medical Corps and his military and civilian assistants. In March, 1941, the civilian advisory component of the board consisted of a clinical pathologist, an oral surgeon, an otolaryngologist, an ophthalmologist, an orthopedic surgeon, a gen-

eral surgeon, a psychometrist, three internists and five neuropsychiatrists. At the beginning, 100 men were examined each day. By February, the number had increased to 250. Approximately 4400 candidates were examined on twenty-two days between November 18, 1940, and February 18, 1941. The results are summarized in Table 1. The

Because the final decision with regard to rejection or acceptance and also the choice of primary and secondary causes for rejection lies, not with examining specialists, but with the medical director of the board, a further analysis is made in Table 3.

Twenty-seven neuropsychiatrists have been employed on the induction board for from one to three days each week. During February, five were on duty each day. Each neuropsychiatrist examined an average of 50 men per day, varying from 35 to 70 according to the individual capacity

of the examiner. The board sat about five hours each day. Therefore, the average time for examination of each candidate was six minutes. The time for examination varied from three minutes for evaluating a normal candidate to ten or fifteen minutes for considering a doubtful case.

It has been said that the neuropsychiatrists on induction boards should insist on a minimum of fifteen minutes for each candidate.⁷ Under the present induction system this is impossible. Examination of 50 candidates at fifteen minutes apiece would require twelve and a half hours. Since it is necessary to deliver the candidates to the reception center on the day of induction, it has been impossible to expend more than five or six hours each day. Experience has shown that no one neuropsychiatrist can do justice to more than 10 men per hour, or more than 50 a day. To enlarge the neuropsychiatric component of the board might cause an undue strain on those available for such duty. Therefore, the problem of the neuropsychiatrists serving on induction boards is to work out a general scheme that may be varied by each examiner in such a fashion as to produce the most effective evaluation in the least amount of time.

As has been stated, a situation exists in which a compromise must be made between thorough and inadequate neuropsychiatric examination of candidates for the Army of the United States. The foregoing outline of the situation and the results obtained to date have led to certain suggestions whereby a practical solution may be reached. Certain general principles must be kept in mind by all examiners. First, because of the national emergency, individual interests must, for the time being, yield to the collective interests of the nation. Secondly, at the present stage of military expansion, the Army needs men who are sound in mind and body. The common fallacy that "the Army will make a man of Johnny" has no place in the present system. The Army is an organization for the defense of the nation and is not to be considered a corrective institution. Thirdly, there are approximately seventeen million eligible men from whom to choose an army of from two to four million men. Finally, the admission of undesirable candidates to the Army not only decreases the efficiency of this branch of defense but also increases the burden on the nation through support of these men by the Army or the Veterans Bureau.

An estimate should be made to determine whether the candidate is vocationally fit for the life of a modern soldier and whether he is mentally durable. Therefore, it is essential that the

medical examiners of the various boards familiarize themselves, as far as possible, with the essentials of neuropsychiatric evaluations,²⁻⁴ the neuropsychiatric requirements for admission to the Army⁸ and the fundamentals of neuropsychiatric examination.⁹ Important signs of instability are addiction to drugs or alcohol, chronic complaints, gastric neuroses, cardiac anxiety, litigation neuroses, fre-

psychiatrists on advisory boards have expressed the opinion that their services are not requested so frequently as might be expected.

The problem confronting the neuropsychiatrist on the induction board is how to make the best decision in the time allowed. A simple neuropsychiatric interview is appended to this article. This is in no sense an attempt at standardization

*One of these was rejected by the medical director
†Indicates some question by neuropsychiatrist as to diagnosis

quent change of occupation or residence, easy fatigability, repeatedly poor scholastic record, prolonged enuresis, urinary dribbling, lack of acquaintances, withdrawal from social contacts, fanatic beliefs and overly aloof attitude during examination. Direct questioning regarding head trauma, unconsciousness, convulsions and nervous breakdowns will often reveal disqualifying disorders. Alert observation of the candidate will often lead the examiner to suspect, if not to discover, disabling personality disorders. Whenever such a suspicion arises, a consultation from a medical advisory board is indicated. Several neuro-

of technic, nor is it offered in the sense of a new approach to the problem. The interview, as outlined, is merely a summary of the type of examination used most frequently by various members of the board. Each examiner uses his particular variant, which he changes to suit individual situations.

Using some variation of the outlined interview as a basis for examination, the neuropsychiatrist employs his power of observation and his previous experience in evaluating the capabilities of the candidate. In doubtful cases a brief consultation with a fellow examiner usually results in a deci-

sion. When necessary, the services of the psychometrist are utilized. At times a consultation with the medical director is useful. In cases in which special technics are necessary for a decision, the candidate is either held for such tests at a later date or rejected with the recommendation that he appeal to a medical advisory board through his local board. In any case of doubt, the question is a matter not so much of diagnosis as of whether the candidate in question will make a good soldier and whether he is mentally durable.

The monotony of the routine, in addition to the continuous rapid interviews, tends to dull the examiner's clinical perception. This is significant because the entire value of the examination depends on the examiner's clinical judgment. Therefore, it is recommended that each neuropsychiatrist examine no more than 10 men per hour, nor more than 50 men per day. Three days out of each week is apparently the maximum effective time available for the average experienced neuropsychiatrist.

SUMMARY

A state of national emergency exists, which requires the entry of large numbers of young men into the Army of the United States. All such candidates are examined in order to eliminate those who are unfit for military service. One of the more important of these examinations is the neuropsychiatric evaluation. A review of the neuropsychiatric problems occasioned by World War I suggests the magnitude of the present problem. Modern warfare demands even greater intellectual and emotional stability in the armed forces. Hence the importance of the neuropsychiatric examinations has increased proportionately. Owing to the limited time available for such examinations, a compromise must be reached between perfection and failure to discover neuropsychiatric disabilities. Certain observations based on examination of 5550 candidates from the Boston Area have suggested means whereby such a compromise may be reached.

Under the present mobilization system there are three channels of admission to the Army. With the exception of the air force, volunteers for enlistment in the Regular Army are not examined by a neuropsychiatrist. A comparison of the number of neuropsychiatric disabilities discovered under the present enlistment system, with the number revealed by trained neuropsychiatrists, suggests that a more thorough examination of the recruits is advisable. Although national guardsmen are examined several times before induction into the Army, a neuropsychiatric evaluation is

not routinely employed. Examination of a group of guardsmen by a neuropsychiatrist revealed that it would be advisable to place more stress on this aspect of the examinations.

Candidates for admission to the Army under the Selective-Service Act are examined at least twice before induction. Examinations by the general practitioners, internists and surgeons serving on the local selective-service boards are sufficiently thorough to discover most of the rejectable disabilities. Examinations by the local boards of Massachusetts have resulted in a rejection of approximately 60 per cent of all candidates examined. It is estimated that about 15 per cent of the rejectees, or 9 per cent of all selectees, were not accepted because of neuropsychiatric disabilities. The medical specialists of the induction board have discovered disabilities in about 20 per cent of the candidates passed by the local boards. Rejection by the induction board for neuropsychiatric disabilities has been only 2 per cent of all selectees; nevertheless, one quarter of the rejections by the induction board has been for neuropsychiatric disabilities. This implies that neuropsychiatric evaluation of the candidates is least thorough by the local boards and most exacting by the specialists on the induction boards. It is therefore suggested that more emphasis might be placed on the neuropsychiatric evaluation of the candidates in their initial examinations and that a final evaluation by trained neuropsychiatrists is necessary to eliminate the less readily detectable but equally important abnormalities.

Certain suggestions are made concerning the technic of a compromise neuropsychiatric evaluation, based on observations made during the examination of 5550 candidates for the Army of the United States.

Only time will tell whether the results of the present mobilization system are worth the care and effort expended. No final conclusions may be drawn from the observations presented in this survey.

ADDENDA

SAMPLE NEUROPSYCHIATRIC INTERVIEW

The following description may give the impression of a lengthy procedure. In practice, the interview may be completed in three minutes with a normal subject. Additional examination and questioning are often necessary, and should not be neglected for the sake of speed in examination. The subject should be carefully observed in every movement and response from the moment he enters the examining room to the moment he leaves. Careful observation of the subject's behavior often yields more clues to abnormalities than the formal examination itself. The examiner should sit with a cloth over his lap about six feet from and facing the door. A desk or table is placed at his right, for instruments and papers. A straight chair is supplied for the subject about three feet in front of and slightly to the left of the examiner. The subject arrives nude or clad in shoes and bathrobe. The following routine ensues:

Come right in. Put your papers on the table. Shake hands with the subject. Take off your robe and shoes. Put them on the chair in the corner. Observe physique, co-ordination, mannerisms and behavior.

Stand here, toes on the line, toes and heels together. Close your eyes. Stand steady. Push the subject. Open your eyes. Stand on one foot, on the other. Observe equilibrium, Romberg and response to push. The latter is especially significant in neuroses and malingering. Elicit abdominal reflexes.

Sit down. Put your feet on my lap, legs extended. Hold your legs still. Perform Babinski maneuver. Put your feet down, toes and heels together. Put your hands in your lap. Elicit ankle, knee, wrist biceps and triceps reflexes. During elicitation of reflexes ask: Have you any trouble with your hands, feet, legs or arms? Have you any numbness or tingling sensations anywhere? Are you troubled with headaches? Backache. D 21

spells? Stomach trouble? How is your appetite? Do you sleep well? Have you ever been unconscious or fainted? Have you ever been knocked out or had your head hurt? If so, ask concerning frequency, sequelae last time it occurred and so forth. Has anyone in your family ever had fits, spells, spasms, convulsions or epilepsy? Have you? Has anyone in your family ever had mental trouble or been in a state hospital because of trouble with his mind? Have you? Have you ever had any nervous or mental breakdowns? Do you get excited easily? Have blue spells? Hold your temper well. How do you get along with the girls? Do you drink? How often do you get drunk? Do you ever have to be taken home? Were you ever arrested for being drunk? Why are you joining the Army? When said in a friendly, curious fashion the answer to the last question is extremely helpful in evaluating the personality.

Examine the pupils for size, shape, equality and reaction to light and accommodation. Say: Show me your teeth. Open your mouth wide. Put your tongue out. Back in. Observe facial muscles for action, tremor and so forth.

Have the subject perform finger-nose test with both hands, eyes open and eyes closed and then say: Grip my hands hard and when I say three, let go suddenly. Grip! one, two, four, six, three! Observe co-ordination, strength and tonus. Put on your shoes and robe. While he is doing so, ask the subject: How far did you go in school? If a graduate of high school or college, ask present occupation. If not: Why did you stop at (the grade)? Did you repeat any grades? Why? At this point if indicated by school record or behavior of the subject, ask suitable questions from the Kent Ten Minute Oral Intelligence Test or similar tests. If the examiner suspects that the candidate's mental age is below requirements he is referred for psychometry. (Candidates with a mental age of less than ten years were considered unfit for the complicated duties of modern warfare.)

PSYCHOMETRICS AT AN ARMY INDUCTION CENTER

CHARLES R. ATWELL, M.A.,* WILFRED BLOOMBERG, M.D.,† AND FREDERIC L. WELLS, Ph.D.‡

BOSTON

IN NOVEMBER, 1940, induction of selective-service men into the Army of the United States began in Massachusetts. The final physical examination of the selectees was carried out at one of three induction boards. The men who came to the Boston Induction Board had been accepted by the various local boards and had ordinarily left their work, taken leave of their families and expected to go directly on to camp on the same day. The medical board making the final physical examination consisted of a group of specialists, all co-ordinated by and under the direction of a medical officer of the Regular Army.§ Among this group of specialists were neuropsychiatrists, whose function it was to give an evaluation of the nervous and mental status of each selectee before this induction.

It became quickly apparent to the physicians conducting this portion of the examination that an essential part of the procedure, in many of the cases, must be concerned with evaluation of "intelligence." The clinical estimate of a psychiatrist of long experience was, of course, of the greatest importance. However, the average time available for each selectee for complete neurologic and psychiatric examination was only six minutes. The large number of men examined in quick succession made it desirable that some more or less objective measure of intelligence level be available in the more doubtful cases. At first, partly by the chance that a copy was in the possession of one of the examiners, the Kent Emergency Ten-Minute Oral Test was used. This was extremely helpful, but it soon became apparent that the answers to the comparatively small group of questions were being passed around from one selectee to another in the dressing rooms; and in addition, even the short time required for this scale interfered with the ability of the neuropsychiatrist to examine the number of men required in the given time, to keep up with the other specialists and to enable the board as a whole to function efficiently.

Decision on each man had to be made immediately, since the selectee was either accepted, sworn in and sent to camp that same day, or re-

jected and sent back to his home. The requirements seemed to be for an objective procedure, well standardized, sufficiently varied to allow for great inequalities of education, sufficiently multiple to avoid the danger of dressing-room discussion, and capable of being administered in a comparatively short time. The basic question is not one of "mental age," still less of "intelligence quotient," but, Is this person's capacity in these respects sufficient for the demands that will be made on him by the Army?

Consequently, one of us (W. B.) sought the assistance of a group of psychologists, consisting of Messrs C. R. Atwell, F. L. Wells, H. Barry, E. A. Lincoln, R. C. Moore, H. C. Patey, L. S. Trowbridge and N. Y. Wessel. This group volunteered to organize a procedure¶ that would answer the above requirements. Not all the selectees appearing before the induction board were examined by the psychologist. Only those were referred who, in the opinion of one of the examining neuropsychiatrists, were below the critical level of capacity for Army demands. The psychologist administered the tests and noted his results, and the selectee was then sent back to the referring physician, who made the final recommendation of acceptance or rejection, on the basis of the test and clinical judgment. Final action on the recommendation lay, of course, in the hands of the Army officer who was medical director of the board.

The chief problem for the group in considering the technics to be used was the limited amount of time available for individual examinations. The question of group tests was naturally considered, but these were looked on as impracticable for both administrative and technical reasons. It was originally believed that the verbal items of the Wechsler-Bellevue Intelligence Scale, supplemented by a vocabulary test, and alternate arithmetic questions from the Alpha Test, would be satisfactory for those cases in which verbal tests could be justified. The selection of nonverbal tests caused more difficulty, but it was expected that the Beta Block Counting Test, the eleven, twelve and fourteen year levels of the Porteus Mazes, and the third, fourth and sixth designs of the Wechsler-Bellevue Block Design Test would be relatively useful.

The original objective was the determination of

*Instructor in psychology, Harvard Medical School; head psychologist, Boston Psychopathic Hospital.

†Instructor in neurology, Harvard Medical School; assistant visiting neurologist, Boston City Hospital.

‡Psychologist to the Hygiene Department, Harvard University; assistant professor of psychology, Harvard Medical School; psychologist, Massachusetts General Hospital.

§A more complete exposition of the general scheme is contained in a paper by von Storch, Pratt, Farrell, Currier and Viets in this issue of the *Journal*.

¶Acknowledgment is hereby made to the medical officers of the First Corps Area and of the Boston Area Induction Board for their co-operation in permitting the setting up of this experimental procedure.

"mental age"* about a critical level of twelve years, the cases seen were referred by the psychiatrists as questionable from this standpoint

Experience brought about a number of modifications in this outlook. It was naturally easiest to deal through brief examination with the relatively few candidates who were of low (under ten years) mental age or high (over fourteen years). Those who constituted by far the greatest number of referrals (mental age scores between eleven and thirteen) formed the major problem. Short cuts, such as printed self-administering material, were generally unsatisfactory, since the subject's performance was unduly handicapped by printed instructions. A probable explanation of this is infrequency of reading among the population examined, with the consequent lack of facility with a comparatively little used skill. The lack of nonverbal material that would be adequate and not time consuming was keenly felt, not only with selectees with foreign backgrounds but also with many who lacked skill with their own language. One example of this difficulty was an American born man who went through the sixth grade of grammar school, but scored only at the ten year level on verbal tests, although he rated fourteen or above on all the nonverbal tests.

No rigid routine of tests should be given, it is

*The use of this symbol was based on practical factors. Its limitations are fairly understood by those technically concerned.

important to have clinicians who are qualified to use their own judgment concerning the techniques that will enable them to give a reasonably accurate approximation of intellectual levels. The tests should be varied to eliminate effects of coaching, which have been observed occasionally. A few questions tapping different mental functions are much more useful than many questions referring to only one type of ability.

Figures are available for four members of the group of psychologists, in a total of sixteen days' examination. During this period, 5010 men were passed through the induction station. Of these, 199 were referred by the neuropsychiatrists for psychometric examination. Of those referred, 79 received a mental age rating of less than twelve, 120 a rating of twelve or over. The number of psychometric examinations in any one day ranged from 4 to 41.

The critical level of twelve was set up as an initial working basis. The Army regulations originally set a mental age of eight as the critical one, and this is obviously low for a modern mechanized army, which places a premium on individual initiative and independent action, in comparatively small groups. The level of twelve may be too high for general use. There is apparently a need for clarification of the situation in the immediate future.

BOSTON MEDICAL LIBRARY

REPORT OF THE PRESIDENT FOR THE YEARS 1933 TO 1940†

I WAS elected President of the Boston Medical Library on January 17, 1933. I consider it incumbent on me to review briefly the salient events of the last eight years. In 1933, the library was suffering acutely from the severe financial depression prevalent at that time. Income from invested funds had dropped from over \$27,000 in 1930 to \$16,000 in 1933—since then, it has dropped to below \$14,000. Income from dues decreased by more than \$1000. The most stringent economies had to be instituted to meet the situation. The staff was reduced, and a 10 per cent salary cut was cheerfully accepted by those remaining. Salaries have since been restored. Evening sessions were omitted for a time, but have since been resumed. The maintenance of the building was by force of circumstances allowed to fall to a meager and inadequate level. Moreover, we were faced in

1933 with a staggering deficit of over \$30,000, which had gradually accumulated over many years, \$18,000 of this deficit being owed to the incomes of various restricted book funds as a result of having spent the money for other purposes, largely for the purchase of periodicals that were considered essential to the library. Furthermore, a cash debt of \$12,000 was owed for binding and periodical subscriptions. This unhappy situation weighed heavily on the minds of the officers of the library.

The most pressing cash debts incurred for binding and periodicals were paid off in cash taken from capital, in addition to a gift of \$2000 from a generous friend of the library, given for the purpose.

The debt to unexpended restricted income of book funds remained an incubus from which there seemed no escape. In spite of a determination at least not to let this sum increase in the future, it

†Read at the annual meeting of the Boston Medical Library, January 28, 1941.

had increased from \$18,000 to over \$23,000 at the end of 1935. Something radical had to be done. This debt of \$23,000 was attacked from several angles and has been gradually whittled down, so that it stands today at the moderate figure of about \$5450.

This has been accomplished in several ways. In the first place, since 1935, current expenditures have been kept rigidly within the incomes of the various restricted funds. We have been aided greatly in accomplishing this by the generous help of many medical societies of Greater Boston in underwriting subscriptions to foreign periodicals. Secondly, competent legal opinion was obtained to the effect that bound periodicals might properly be considered books. The adoption of this definition by the Board of Trustees permitted the cancellation of a considerable amount of the debt to the restricted book funds that had been incurred in previous years for periodicals. Thirdly, administration expenses for handling investments and funds that had been solely borne by the unrestricted funds were charged pro rata to the restricted funds as well, and these charges were carried back for a number of years. Finally, cash received from unrestricted gifts was allocated and spent directly toward the extinguishment of this debt.

In the latter part of 1935, the library received an unrestricted bequest of \$25,000 from the estate of Mrs. Amelia Jackson Sargent, a sister of Oliver Wendell Holmes. This was indeed a lifesaving gift. It permitted paying off in toto the remaining binding bills of previous years, as well as a note of \$3000 to the State Street Trust Co. The remainder was expended for renovation of the main building and the erection of two tiers of steel stacks in the annex. These improvements were urgently needed and put the building in excellent working condition for the first time in many years.

In addition to this generous bequest, the library has received during the last eight years the following gifts and bequests in round numbers: in 1934, a gift from Dr. John W. Farlow of \$2000, unrestricted; in 1936, a gift of \$10,000 from the Wadsworth family (this was given to establish and maintain suitable offices for officers of the Library on the first floor, as a memorial to Dr. Oliver F. Wadsworth, and his son, Dr. Richard G. Wadsworth); in the same year, a bequest from the estate of Dr. Malcolm Storer of \$2000, unrestricted; in 1936, a bequest from the estate of Dr. John W. Farlow of \$10,000, unrestricted; in 1939, a gift of \$1000 from the friends of Dr. George H. Bigelow

as a memorial fund for the purchase of books on public health. In addition to these larger benefactions, a constant stream of gifts and bequests of books, manuscripts, portraits and medical memorabilia of all kinds from numerous friends has added much to the value of our collections.

In 1937, the by-laws of the corporation were amended: a board of trustees was created and the terms of office for all officers, except the librarian, were limited.

During the last three years, through the efforts of the director, Mr. James F. Ballard, the aid of several WPA projects has been secured for the library. By this means a vast amount of important work has been accomplished at minimal expense—work that otherwise could not have been done. The mass of periodicals and serials accumulated during twenty years, piled high in the basement, was examined and sorted. Items wanted by the library were catalogued and filed, the remainder disposed of by exchange or sale. Over 397,000 items were examined, 25,000 added to the files, over forty tons of material disposed of by exchange, and an even greater tonnage sold for waste paper. Forty-one thousand books were examined and disposed of, and 19,000 periodical and serial titles were checked for the new edition of the *Union List of Periodicals and Serials*. Three hundred and seventeen thousand dissertations and theses, as well as several thousand bound volumes, have been examined, catalogued and shelved.

The catalogue in Holmes Hall, which was in a sad state of dilapidation, was renovated, cleaned and partly retyped. Nearly sixty-three thousand volumes were vacuum cleaned and dusted. This work is still going on. In spite of the imposing amount of work done, much still remains, and I cannot say truthfully that our basement has as yet been transformed into a model of orderliness.

During the last two years, with the co-operation of the *New England Journal of Medicine*, over 90 per cent of the books received for review have, through the kindness of the reviewers, been turned back to the library. This has been a very great help, since it puts on the shelves a considerable number of the newest books that otherwise would have had to be purchased.

During the last year, the Committee on Post-graduate Instruction of the Massachusetts Medical Society has provided funds for the equipping of a bibliographical traveling library in connection with the courses offered. This joint enterprise, whereby the facilities of the library are extended to

outlying districts, is in line with a policy that the library has long desired to adopt but has been unable to undertake hitherto for lack of funds. It is an interesting experiment of much promise.

Cordial relations have been maintained between the Boston Medical Library and the libraries of the three large medical schools of Boston, and also with the libraries of the large hospitals. Coordination of policy with the library of the Harvard Medical School has obviated competition and the duplication of expensive items.

While the library has been struggling during the last eight years properly to maintain its services and its building, a steady and noteworthy accretion to its collections of incunabula and historical items has been going on, as the result of judicious expenditures from our funds restricted to these purposes, so that today the library in this respect has attained an outstanding position in the country.

The use of the library has shown a steady growth during the years, and the needs of students, scholars and the profession, in general, have been met quite satisfactorily, I believe, through the sustained efforts of the small but devoted staff.

Although, on the whole, considerable progress has been made during the last eight years in vari-

ous directions, many serious problems remain. We are still terribly overcrowded and understaffed, and there is a crying need for the completion of the steel stacks. The financial support of the library is inadequate, depending as it does largely on its relatively small membership, which has remained practically stationary for years, in spite of vigorous efforts to the contrary.

The relation of this library to the libraries of the medical schools and hospitals of this community, and to the profession in general, is a difficult problem that awaits satisfactory solution. These smaller libraries provide for the ordinary needs of their clientele, so that many doctors do not feel the need of becoming members of the Boston Medical Library. What the ideal setup should be for this community needs serious study and wise decision. Preliminary steps in this study are already under way.

We are indeed fortunate in possessing a splendid library, inherited from our predecessors and built up by the unremitting effort and generosity of many wise and devoted friends of medical literature; such a precious heritage must not be allowed to decline, but must be fostered, cherished and sustained by the medical profession.

LINCOLN DAVIS, *President*

REPORT OF THE LIBRARIAN FOR THE YEAR 1940*

IN 1876, John Shaw Billings, then librarian of the Army Medical Library, wrote, in commemorating a century of American medicine: "The medical library of most promise in Boston is that of the Medical Library Association, which, though only a year old, has about 3000 volumes, and will probably rapidly increase." He was right about the "library of most promise," for recognition was soon evident, and the medical collection of 11,000 volumes in the Boston Public Library was transferred to us. Other medical books followed, and the Boston Medical Library carried out the second injunction, mentioned by Billings, and did "rapidly increase." In 1940 we find ourselves with over 300,000 books and pamphlets; we are increasing yearly at a rate of 9000 to 12,000 items. In another twenty years we shall reach the half million mark, a sizable library by any standard, and a collection needing all our stack space now available or projected. We are now, sixty-four years after Billings's remarks, still having "growing pains," apparently a perpetual and normal state for an active

library. Our next major endeavor should be to complete the stacks in the annex provided for that purpose.

During the year, 1940, not only has the library grown in volume with the addition of about 3500 books and 9000 pamphlets, but the high quality of our accessions, a standard set by my distinguished predecessors, has been maintained. When I look over our list of rare books and manuscripts acquired during the year, I cannot help believing that we are fortunate beyond the dreams of many of our friends, both past and present.

When Bodley set up his staff at the library door at Oxford in 1597 he began the restoration of an ancient foundation, soon making the library into one of the most famous in the world. He left his own account of the matter:

I found myself furnished with such four kinds of aids as, unless I had them all, I had no hope of success. For without some kind of knowledge, without some persueability to go through with the charge, without good store of friends to further the design, and without special good leisure to follow such a work it could not but have proved a vain attempt.

*Read at the annual meeting of the Boston Medical Library, January 28, 1941.

Those same cherished "four kinds of aids" have made the Boston Medical Library what it is today, and without them your librarian could never have reported such important additions to our collection as I shall briefly mention.

Of manuscripts, we continue to add those of particular New England interest—health reports, letters, account books, bills for drugs and for services and all matters pertaining to the practice of medicine by our forefathers. The Boston Medical Library is the natural home for such items, and many have been received by gift. The librarian, however, has not hesitated to buy valuable material of this type, knowing well how time devastates the fugitive sheet that the future historian may consider of prime importance. Rich, too, have been our acquisitions of English imprints, fourteen printed before 1640 and four more before 1700. To our fifteenth-century books, now one of the greatest collections in the country, we can also report fourteen additions, all placed on our shelves since the publication last year of the *Second Census of Incunabula* by Miss Stillwell.* They are now entrusted to our care, precious relics of early printing and medical history. For them and their like, a treasure room is urgently needed, a place where the indispensable tools of scholarship, many of them unique, can be properly housed. To them must be added the early American imprints, reflecting the beginnings of medicine in our country. Not a few of these also found their way to our shelves in 1940. A number of important collections of books, moreover, have been acquired, particularly the Baumes Collection of French medical tracts, the Carsten Collection (850 volumes), illustrative of the physician in literature and of literary doctors, and the twenty-odd complete editions of the writings of Domenico Cotugno.

These acquisitions all resulted from the "four kinds of aids," just as valuable in our times as in Bodley's. The "some kind of knowledge," resides largely in the mind of the director, Mr. James F.

Ballard, whose quick recognition of the value of a book or a collection, based on long experience and a natural flair for book acquisition, again leaves the library in his debt. Without him, the library would indeed be a poorer place. Our "purse-ability," not large and yet greater than all but a few medical libraries in this country, gives us strength and a certain latitude of action. In book buying, to be able to acquire promptly often means securing the best. Since we are ever watchful of the market, the library rarely misses what our small funds can pay for. War years offer many unusual opportunities, however, and we do not anticipate any difficulty in 1941 in using all our book fund for worth-while purchases. Bodley's third aid, a "good store of friends to further the design," has never been wanting. What better friend has the Boston Medical Library ever had than our retiring president? May his interest continue from afar, but not too distantly afar, and for many years. And finally, Bodley's "special good leisure to follow such a work." There, indeed, we are weakest. Few have leisure today. Work of this type, for most of us means "nights, holidays and Sundays." But what better use of time? A report, a committee meeting or even the lowly book review serves to add to our rewards, those intangible assets so difficult to assess, but so potent in the advance of civilization. The most civilized country is the one that has produced the most great men. Has any man ever been great without a love of books? What country has achieved distinction, moreover, without libraries? Is not Boston a better Boston because our forebears collected the medical literature of their day, added to it the writings of the past and saw to it that a medical library should endure and grow? Well did our fathers of the Medical Library Association of 1875 realize the value of Bodley's four aids, and by the use of knowledge, purse-ability, friends and leisure set up a broad foundation on which we are still building. The librarian today sees no reason to change the four aids; on them rests the future of our institution.

HENRY R. VIETS, *Librarian.*

**Incunabula in American Libraries: A second census of fifteenth-century books owned in the United States, Mexico and Canada.* Edited by Margaret Bingham Stillwell. New York: The Bibliographical Society of America, 1940.

MEDICAL PROGRESS

PRACTICAL ASPECTS OF SURGICAL SHOCK*

J. ENGLEBERT DUNPHY, M.D.†

BOSTON

TODAY, with half the world at war, the subject of shock is of particular interest. However, even in times of peace, it is of primary concern to both physician and surgeon because not only is it a frequent determining factor in the outcome of many surgical and medical conditions, but, being a reversible phenomenon, it offers hope of cure if recognized early and treated properly. This review is intended to focus attention on those aspects of the subject that are of importance in everyday surgical practice.

Shock has been described as a clinical condition, the characteristics of which are pallor, a cold, moist skin, a rapid thready pulse, shallow respirations, an appearance of anxiety that soon becomes one of apathy, a subnormal temperature and a low blood pressure. It is this clinical state or syndrome that quite properly comes to mind when the term "shock" is used. The time has come, however, when shock must be suspected, diagnosed, if possible, and treated before the development of this syndrome. The familiar picture of shock must be regarded as evidence of uncompensated or late shock. This is by no means a new conception. It was emphasized by Cannon¹ nearly two decades ago. Keith,² discussing wound shock in World War I, speaks of "compensated" and "uncompensated shock." The unreliability of the pulse rate and blood pressure as indications of shock, both experimental and clinical, has been stressed many times.^{3,4,5} Nevertheless, although not new, the conception of compensated shock requires a wider clinical application. It is fair to state that shock frequently plays an important and often unrecognized role in the morbidity and mortality rates of appendicitis, intestinal obstruction, perforated ulcer, peritonitis from any cause, burns, severe fractures and acute or subacute loss of blood.

It is generally accepted today that an essential feature of shock, regardless of cause, is a disparity between the amount of circulating blood and the size of the vascular system. This can be brought about either by a loss of fluid from the circulation or by an uncompensated increase in the size of the vascular bed. The size of the vascular sys-

tem may be increased by such sudden loss of vasomotor tone as occurs in fainting and under spinal anesthesia, or it may be increased by widespread capillary dilatation and injury from bacterial toxins, certain anesthetics or histamine. Shock due to dilatation of vessels is referred to as "neurogenic shock."⁶ When there is actual injury to capillaries and vessels the term "vasogenic shock" may be used. By and large both neurogenic and vasogenic shock are characterized by a low blood pressure, are more easily recognized and are less serious than shock secondary to an actual loss of fluid from the vascular system (so-called "hematogenic shock").⁶ This loss may occur in many ways: as blood in hemorrhage; as plasma in burns, peritonitis, crushing injuries and intestinal obstruction; and as water in diarrhea, vomiting or sweating. Fluid may be lost from the blood stream into tissues as a consequence of generalized capillary injury. This may be a primary phenomenon, as described above, producing vasogenic shock, or it may be secondary to a prolonged reduction of the blood volume, reduced blood flow and anoxia.

Usually there are many factors in shock, some a primary cause of the reduced blood volume, others secondary to it. Prolonged peripheral vascular collapse due to nervous stimuli (neurogenic shock) may result in actual injury to capillaries (vasogenic shock). When there is widespread capillary injury not only is the vascular bed increased in size but fluid is lost from the circulation into the viscera, thus bringing about an actual reduction of the blood volume (hematogenic shock). Conversely, if the blood volume is reduced by loss of fluid from the circulation, as in hemorrhage, this leads to reduced volume flow, a reduced delivery of oxygen, tissue anoxia and widespread capillary injury. Thus, hematogenic shock leads to vasogenic shock. The situation has been well depicted by Moon⁷ as a vicious circle. His ideas and those of Blalock are reproduced in a modified form in Figure 1, in which a reduction of the effective blood volume is shown as the essential factor and pathologic changes in the viscera as a final result of shock.

The pathologic changes that occur in the viscera are not of a specific character, but represent the end result of capillary injury and tissue anoxia.⁸

*From the Laboratory of Surgical Research, Harvard Medical School, and the Surgical Service, Peter Bent Brigham Hospital.

†Instructor in surgery, Harvard Medical School, associate in surgery, Peter Bent Brigham Hospital.

There are dilated, congested capillaries, capillary hemorrhages, edema and in some cases degenerative changes in parenchymatous tissues throughout the lungs, liver, kidneys and gastrointestinal tract. It is likely that, once well established, these pathologic changes are irreversible. Treatment, if it is to be effective, must be instituted before generalized tissue damage occurs.

At this point the blood-pressure changes in shock require further comment. If the shock is primarily due to factors that produce vascular re-

in a few minutes both return to comparatively normal levels and may remain there for long periods.⁸ However, from the moment of injury there is a rapid and progressive reduction of the blood volume. Indeed, in severe shock in which death occurs within eight to twelve hours, the principal reduction of the blood volume occurs within two or three hours of the injury. This is shown in Figure 2. It should be noted that after three hours the blood volume falls to two thirds of its original total. There is a marked rise in the hematocrit

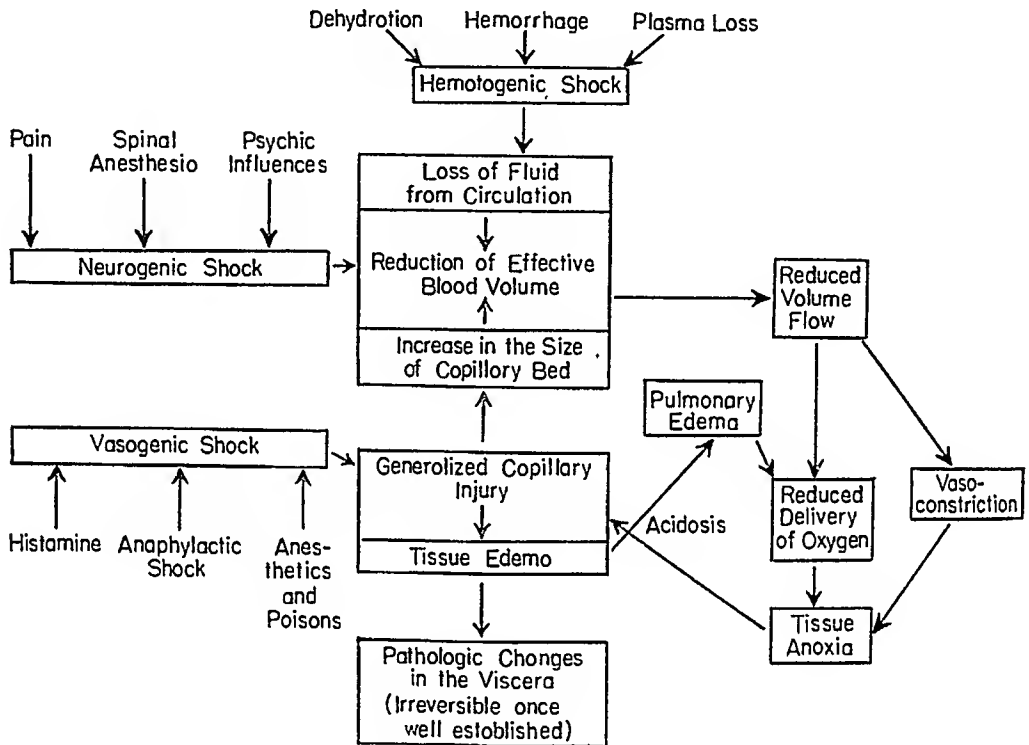

FIGURE 1. *The Vicious Circle of Shock.*

The classification of shock as given by Blalock is combined with the ideas of Moon to provide a more complete picture of the many variables that enter the shock syndrome.

laxation or generalized capillary injury, there will be a low blood pressure. This occurs in such conditions as spinal anesthesia, histamine shock and barbiturate poisoning. If the shock is a consequence of loss of fluid from the blood stream, as in hemorrhage, burns, peritonitis, intestinal obstruction or mechanical injury, there may be a low blood pressure at the onset as a consequence of pain and psychic influences. If the shock is very severe, there may be no reaction from this fall in pressure, but usually after pain and fear have been relieved the compensatory mechanisms of the circulation are such that the usual clinical manifestations of shock do not appear. For example, if an anesthetized animal is subjected to mechanical or thermal trauma there is an initial fall of blood pressure and elevation of the pulse rate, but with-

reading, indicating hemoconcentration, but very little alteration in the pulse rate and blood pressure. If one were to examine the animal at this point, noting only the levels of the pulse, respiration and blood pressure, a diagnosis of shock would be untenable. Yet, this animal is in a state of grave shock, as evidenced by the reduction of the blood volume. Under the conditions of experiments of this type a fall in the blood pressure indicates a failure of the compensatory mechanisms of the body and impending death. It was shown years ago that a similar response may occur in experimental hemorrhage.⁹

In man it has been shown that as much as 500 to 1000 cc. of blood may be removed from a volunteer subject without significant alteration of the pulse or blood pressure, or the appearance of pal-

lor, thirst or a sensation of anxiety.¹⁰ In fact, there may be so little change in the physical appearance of the subject at rest that a physician unaware of the removal of the blood would pronounce him fit to give transfusion. Yet, the rapid removal of an additional 500 cc. of blood might prove fatal. So it is with many clinical conditions. A familiar example is the free perforation of duodenal ulcer. The patient who is seen within half an hour after the onset is often described as being in severe shock. He is prostrated with pain. There are marked pallor, a rapid pulse, a moist, cold skin, a subnormal temperature and a low blood pressure. After the pain is re-

clinical picture, it places a serious and unnecessary burden on the circulatory system that, added to other factors, may prove the deciding point in a fatal issue. It behooves the surgeon, therefore, to anticipate and correct such reductions of the blood volume before the signs of uncompensated shock appear.

The value of early treatment in shock is well known. The importance of instituting therapy in so-called "compensated shock" before the usual clinical manifestations of shock appear has not received adequate attention. Yet it is in this period that treatment is most likely to be effective. In an experimental study of shock due to severe

FIGURE 2. *The Course of the Changes in the Hematocrit, Blood Pressure, Plasma Volume and Pulse Rate in Experimental Shock Due to Severe Burns.*

A fall in the blood pressure is a late sign, indicating collapse of the compensatory mechanisms of the body.

lieved and compensation is established, the color of the skin returns, the pulse improves and the blood pressure returns to normal levels. At this point one is apt to say that the patient has reacted from his shock, or if he first enters the hospital in this state, it may be said that he is not in shock. Yet this patient may be in severe shock. He may be in the same condition as the experimental animal referred to above, or the subject who has just given a 1000-cc. transfusion. He is in a state of compensated shock. The reduction of the blood volume is such that although the usual clinical signs of shock are not manifested, there is a heavy burden on the circulation that, when combined with the effects of anesthesia and a surgical operation, may prove fatal. So it is with many clinical conditions, such as appendicitis, peritonitis and intestinal obstruction. The factor of shock is present, and even though it is not severe enough to produce the classic

burns it was shown that if treatment was delayed until the blood pressure had fallen, it was of no avail; and even if such treatment restored the blood volume to normal, there was no striking prolongation of the life of the animals and no alteration of the usual pathologic changes in the viscera.¹¹

How, then, may shock be recognized before the usual clinical signs appear? The significance of hemoconcentration as an early sign of shock has been emphasized by Moon.⁷ As shown in Figure 2, the rise in the hematocrit in severe thermal trauma closely approximates the fall in the plasma volume. This sign is unquestionably of value and may appear long before there are significant alterations of the pulse or blood pressure. On the other hand, it is by no means pathognomonic, and since control observations taken before an injury are not possible in the clinical treatment of shock, the initial level of the hematocrit is often

of little value. A low hematocrit due to anemia may rise to a normal level as a consequence of hemoconcentration. Moreover, concealed hemorrhage is so often a complicating factor in shock that the hematocrit levels are very difficult to interpret. Finally, as Weiss¹² has emphasized, in the well-hydrated patient, plasma may be lost into an area of injury but hemoconcentration may be prevented by fluids entering the circulation from the tissue spaces elsewhere in the body. Thus, hemoconcentration may not be manifest even in traumatic shock uncomplicated by hemorrhage. However, it is true that a changing and particularly a rising hematocrit is of great significance in the early stages of shock.

Scudder and his associates^{13, 14} point out that four determinations are essential in evaluating the early stages of shock — the hematocrit, the specific gravities of whole blood and plasma, and the level of the serum protein. By means of these data he believes that the onset of shock can be anticipated. The essential feature of these tests is the use of the falling-drop method to determine the specific gravity of plasma, from which the level of the plasma protein can be calculated. This provides a rapid and accurate check on the level of the serum protein. The protein level is a valuable check on the hematocrit and provides information of considerable importance. It furnishes evidence of protein loss as well as hemoconcentration and may give an index of hemoconcentration in the presence of anemia. However, not infrequently in the early stage of shock combined with hemorrhage, these figures may be within normal limits. For this reason, although such determinations are of inestimable value in the appraisal of early shock, it is a mistake to consider them as an accurate and infallible guide to the state of the circulation. The details of the history, the character of the illness, the quality as well as the rate of the pulse, the general state of hydration and the color of the skin and mucous membranes provide information of great value to the careful observer. Emphasis must be placed on an evaluation of the total picture rather than on the results of any laboratory data if one is to recognize the earliest manifestations of shock.

It is not sufficient to urge early therapy in shock. The quality and quantity of the therapy are of extraordinary importance. Treatment is largely confined to efforts to remove causative factors and to restore the blood volume to normal. Although there is experimental evidence to support the use of adrenocortical extract, various drugs and high concentrations of oxygen, these methods must be looked on as only of contributory value. The chief requisite is to restore, if possible, the lost

fluid. Treatment therefore depends on the type of fluid required. Although there is considerable overlapping, three broad groups may be recognized: dehydration shock, in which the principal requirement is water and salt; shock produced by hemorrhage, in which blood is needed; and finally, shock due to loss of plasma, for which plasma is the best replacement. In recognizing the type of fluid replacement required, determination of the hematocrit and serum protein is of great value.

Dehydration shock is characterized by severe depletion of water and electrolytes. It is encountered in its most classic form in Asiatic cholera,¹⁵ but in lesser degrees is common in clinical practice,¹⁶ particularly in high intestinal obstruction, in some cases of peritonitis and in prostrating diarrhea or fever. The changes in the blood consist in an elevation of both the hematocrit and the serum protein and usually a fall in the serum electrolytes. The type of fluid required is physiologic saline or lactate solution, depending on the relative losses of chloride and sodium ions. Treatment of this form of shock is essentially that of dehydration, and the details of treatment have been well worked out by many investigators.¹⁶⁻¹⁹ Emphasis should be placed on the dangers of giving an excess of saline solution in the treatment of dehydration shock.¹⁸

Shock due to hemorrhage is well understood. In its acute form it is characterized by a fall in the hematocrit and little or no change in the level of the serum protein. The treatment, of course, is to restore the lost blood by transfusion, but the frequency with which this may be necessary is not fully appreciated. The fact that there has been no gross hemorrhage during a prolonged surgical operation is no indication that there has not been a considerable loss of blood. The amounts of blood taken up in towels, swabs and sponges may be enormous, and it should be axiomatic that at least one transfusion is advisable following extensive surgery, even though there has been no gross hemorrhage. Although, as previously pointed out, patients may compensate well for considerable losses of blood, the sick surgical patient should not be required to face this additional and unnecessary hazard when the lost fluid can readily be replaced by transfusion. As Blalock⁶ has said, "There is probably no one procedure which, in recent years, has had a greater influence in reducing the mortality connected with accidents and operations than the more frequent use of blood transfusions."

The third and most important form of shock is that in which loss of plasma is the principal factor in the early reduction of the blood volume. This occurs in burns, in severe crushing injuries and,

to a lesser extent, in peritonitis and intestinal obstruction.²⁰ It is characterized by an elevation of the hematocrit but with only slight or no increase in the level of the serum protein. A normal concentration of protein in the presence of hemoconcentration is indicative of loss of protein and is a clear indication for injection of serum or plasma. The common practice of using physiologic saline solutions in shock accompanied by loss of plasma must be deprecated. Unless there are specific indications for its administration, as described under dehydration shock, more harm than good may result. The possible dangers following the use of saline solution in shock were pointed out long ago by Beard and Blalock.²¹ They showed that animals that had been given saline solution in shock often appeared worse after the infusions were stopped than if no treatment had been given.

There are three reasons why such a solution is harmful. First, although the injection produces a temporary rise in the blood volume with apparent improvement in the patient, not only is this of short duration but it is accompanied by such marked dilution of the blood that the serum protein is reduced to an edema level. Secondly, saline solution leaks out of the blood stream, not as such but as dilute plasma, thereby actually increasing the rate of protein loss. Finally, as a consequence of the loss of protein, the osmotic pressure of the blood is lowered and fluid leaks out of the blood stream, not only into the areas of injury but throughout the viscera, thereby accentuating the pathologic changes in the viscera.²¹ Thus, the use of saline solution in shock of this type not only produces no permanent rise in the blood volume but eventually leads to pulmonary edema and congestion, with a concomitant decrease in the aeration of the blood, thereby adding an additional factor to the vicious circle of shock, as depicted in Figure 1.

The efficacy of serum or plasma injections in shock has been demonstrated by many investigators.²²⁻²⁵ Emphasis has been placed on the fact that the level of serum protein is sustained, the osmotic pressure of the blood is not lowered, less fluid leaks out of the vascular system, and thus the beneficial effects are more permanent. It should be pointed out that in severe shock the beneficial effect of a single injection of serum or plasma may be no more permanent than that of saline solution.²¹ Plasma is lost into the site of injury, particularly in severe burns, so rapidly that within a few hours the blood volume again falls to a shock level. In severe shock, therefore, enormous amounts of serum or plasma may be necessary. In experimental shock due to thermal

trauma, it has been demonstrated that a continuous infusion of plasma at the rate of about 100 cc. per hour is necessary to maintain the blood volume at a normal level during the first ten hours.²¹ Elman²⁶ recommends giving plasma in amounts up to 1500 cc. during the early stages of severe burns, and Mahoney²⁷ has had occasion to give as much as 3000 cc. to a patient undergoing a one-stage resection for cancer of the head of the pancreas. How long plasma continues to be lost from the circulation in severe shock is probably variable. Elkinton and his associates²⁸ suggest that it continues for as long as forty hours. In any individual case, emphasis should be placed on frequent determinations of the hematocrit and serum protein, and continuation of therapy so long as there are indications.

Finally, it should be stressed, that one frequently encounters dehydration and blood and plasma loss in the same patient. Under such circumstances careful evaluation of the clinical and laboratory evidence is necessary if the total picture is to be correctly appraised and proper treatment instituted.

SUMMARY

Because of the compensatory reactions of the body the usual clinical signs are often absent in the early stages of shock due to dehydration, hemorrhage or loss of plasma. Successful treatment depends on the recognition of shock before the usual clinical signs appear. Varying degrees of shock of this type are frequently encountered in many common surgical conditions, notably peritonitis, intestinal obstruction, burns, trauma and hemorrhage. A correct appraisal of the condition and the institution of proper replacement therapy are dependent on a careful study of the patient as a whole, as well as an evaluation of certain essential laboratory data.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27211

PRESENTATION OF CASE

A fifty-seven-year-old married nulliparous woman entered the hospital complaining of abdominal pain, nausea and vomiting.

Six years before admission, the patient had an attack of pain in the right upper quadrant of the abdomen, which was accompanied by nausea and vomiting and lasted for five days. Since that time she had had attacks of biliousness, characterized by epigastric fullness, nausea, headache and dizziness, which occurred perhaps once a month, followed by the ingestion of greasy foods, and were prevented by the elimination of these foods from her diet. Of recent months she had been slightly constipated, and one week before admission noticed the onset of general malaise and nausea. During the next three days the patient took several doses of saline cathartics with good results, but three days before admission she was seized with a crampy mid-epigastric and right upper-quadrant pain accompanied by abdominal distention and the vomiting of "yellow bile." Soon the pain became severer and more constant, and spread to involve the entire upper abdomen, but there was no constipation. Her physician administered a "strong hypodermic." The following day her condition was unchanged; pain and vomiting were still present, there were no bowel movements and her physician gave another hypodermic injection. The day before admission the pain shifted to the lower abdomen and was constant, colicky without radiation and located chiefly in the left lower-quadrant and suprapubic regions. When the patient attempted to rise from bed, she suffered severe pain in the rectum. Her physician recorded a temperature of 100°F. and found tenderness, especially in the left lower quadrant, with generalized rebound tenderness. During the day the patient had several bowel movements. On the morning of admission vomiting reappeared, the pain had eased slightly, but abdominal tenderness was more pronounced and she passed small amounts of gas by rectum. At no time had there been chills, jaundice or change in the color of her stools. During the illness there was some frequency with cloudy urine, but no reddening had been noticed.

The patient had had the usual childhood diseases, including scarlet fever and diphtheria. The family history was irrelevant.

On examination the patient was well developed and well nourished, sallow and drowsy. Her tongue was dry and coated, the breath having a questionably uremic odor. The heart and lungs were normal; the blood pressure was 100 systolic, 70 diastolic. The abdomen was somewhat distended, and there was no spasm; however, there was a slight generalized tenderness most marked in the left lower quadrant, where there was rebound tenderness. Peristalsis was hypoactive, with some high-pitched sounds, but no true tinkling. On pelvic examination, movement of the cervix produced considerable pain. Tenderness was present in both vaults, more marked on the left, and in each there was a small tender mass situated posteriorly, the one on the left being more prominent. Rectal examination revealed a large rectal shelf, with a well-defined, firm fixed mass posteriorly on the left. The feces were guaiac negative.

The temperature was 100°F., the pulse 95, and the respirations 25.

The urine was normal. The blood showed a red-cell count of 3,700,000 with a hemoglobin of 70 per cent, and a white-cell count of 12,600 with 89 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 33 mg. and the protein 5.3 gm. per 100 cc., and the chlorides 97.5 milliequiv. and the carbon dioxide combining power 25.6 milliequiv. per liter.

A flat abdominal x-ray film showed gas-filled dilated loops of small bowel occupying the lower abdomen. The colon was practically empty.

An electrocardiogram showed a normal rhythm at 110 with a PR interval of 0.14 second. T₁, T₂ and T₃ were low or diphasic.

The patient was given intravenous fluids, and her condition remained unchanged until the second hospital day, when the abdomen was softer, and the peristaltic sounds infrequent and of normal pitch; a soft tender mass could be palpated in the left lower quadrant. The next day she was almost comatose, tracheal gurgles were present, and the temperature had risen to 104°F.; intravenous fluids were discontinued. A flat plate of the abdomen showed a decrease in dilatation of the loops of the small intestine.

Five days after admission the patient was much improved, the abdomen was soft and she passed three loose stools, but the white-cell count had risen to 25,600. From the time of entry, attempts to pass a Miller-Abbott tube beyond the stomach had failed, but on the fifth day it was visualized

within the jejunum and began to drain moderate amounts of thin brownish fluid. The next day tenderness had decreased in the left lower quadrant, but pelvic examination revealed an irregular fluctuant mass filling the pelvis to the brim and lying anteriorly and superficially on the left; there was only moderate tenderness. The loose stools continued, were composed of brown liquid containing mucus and gave a ++++ guaiac reaction. Examination of the chest revealed dullness, squeaks and groans, with increased vocal fremitus at the angle of the right scapula; the sputum contained a Type 20 pneumococcus. An x-ray film taken with a portable machine showed elevation of the right diaphragm, but no visible intrapulmonary disease except for a few areas of atelectasis on the right side. Chemotherapy was instituted, and in two days there was marked clinical improvement and the patient was able to take fluids by mouth, the temperature gradually dropping to normal and the white-cell count to 12,000. At the end of this period, however, she became apathetic, the temperature climbed to 103°F. and there were signs of consolidation in the right lower lobe, with rales at the left base. Another chest plate showed an area of density along the right border of the heart apparently in the medial portion of the middle lobe, which was believed to be due to partial atelectasis.

Two days later the patient was slightly disoriented and dyspneic, with a weak pulse. The abdomen was distended and somewhat spastic, with a little rebound tenderness. The firm mass in the left lower quadrant had increased in size, and peristalsis was hyperactive and tinkling; small amounts of feces continued to drain from the rectal tube. The cervix was fixed, and the firm mass, apparently continuous with the uterus, filled the pelvis. Both legs were edematous, the left more than the right. An abdominal film showed a small amount of air but no dilatation in the loops of the small intestine. Death occurred on the seventeenth hospital day, the temperature being 104°F., the pulse 130, and the white-cell count 18,000.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: Dr. Lingley, will you please show us the x-ray films?

DR. JAMES R. LINGLEY: This is the first abdominal film, showing gas-filled loops of slightly dilated small bowel.

DR. ALLEN: Can you see a gallstone anywhere?

DR. LINGLEY: No; there are no opaque stones. This is a later film, taken with a portable machine, which still shows some gas in the small bowel.

There is possibly a little less dilatation than previously. I do not see the mass spoken of in the pelvis on any of the films. This is the first chest film, showing a very high right diaphragm and some areas of density in the medial portion of the lung. This film, taken seven days later, shows an increase in the pulmonary process, and I believe that this density could be due to either atelectasis or pneumonia.

DR. ALLEN: Dr. Lingley has not been as much help as I hoped he might be. The patient, a fifty-seven-year-old woman, came to the hospital a week after the onset of some sort of acute abdominal illness. We naturally think of this long story of gallstone colic in relation to the present illness, and wonder whether by any chance a gallstone could have eroded through into the duodenum or into the small bowel somewhere to produce this picture. There are a good many things against this possibility. The history is not quite long enough. It usually takes about three weeks of right upper-quadrant difficulty or signs of an inflammatory process before the stone erodes into the intestines. When it gets there, it may produce intermittent obstruction and finally pass by rectum. Usually, however, the obstruction is very definite, and in this case it was never complete. In spite of the dilated loops shown on entry, this does not look like the type of obstruction that one gets with gallstone ileus. Besides, the patient had had good evacuations with saline cathartics, and also some movements after she had stopped taking cathartics.

What else could we have that might be associated with her probable gallstones? In a case of this sort, I think we should mention the possibility of pancreatitis, which the long history of epigastric pain and vomiting strongly suggests. I should have expected that the patient, however, if she had had pancreatitis, would have had a boardlike abdomen on admission and would have been more ill, and also that she would not have run the course described in the record. For instance, it would have been unlikely for her to develop a large pelvic mass in association with pancreatitis. I am therefore inclined to believe that this episode was not in any way related to her gall-bladder disease.

The next question that we must try to decide is whether this is a mechanical or an inflammatory obstruction; whether or not it is based on a malignant background is not so important. Obviously, in the minds of the men looking after this patient, there was some doubt whether she did have a mechanical obstruction and not just a secondary ileus, so that they started to decompress the up-

per intestinal tract quite correctly with a Miller-Abbott tube. I think the facts that she continued to have evacuations and that she had so much inflammatory reaction as evidenced by the temperature and white cell count, with the development of a mass in the lower abdomen, probably rule out mechanical obstruction such as we see associated with a band of adhesions. She had had no previous operations, which does not rule out mechanical obstruction but is one point against it. I believe we have to offer inflammation as the basis of obstruction. One condition that simultaneously produces the signs of intestinal obstruction and inflammation is an inflammatory process in Meckel's diverticulum, although I should have expected the course to be slightly different if this were an inflamed Meckel's diverticulum. However, the patient could have had the abdominal pain, the vomiting, the partial obstruction and the inflammatory pelvic mass from such a lesion. Fifty-seven is a little old for a Meckel's diverticulum to get a person into trouble.

There is another disease that I believe we must consider very seriously, although there are a great many odds against it, namely, diverticulitis of the sigmoid, and I have a feeling from the way the record reads that the patient was treated for this condition. She had epigastric pain at the onset, which is in order. Her pain and tenderness came down to the lower abdomen. Things were a little more concentrated on the left than on the right. The drawback to that diagnosis, as I see it, is this: if a diverticulitis of the sigmoid is sufficient to cause an abscess, complete large bowel obstruction occurs. This woman never had it, and I do not believe we can overlook that one feature. When she developed the mass in the pelvis she behaved like a patient who gets a residual pelvic abscess following appendicitis that produces diarrhea and the output of a great deal of liquid fecal matter.

We have no reason to suspect that the difficulties arose from any of the pelvic organs. The pelvic findings toward the end would not have been so masked and obscure as they appear to have been in this story.

The possibility of neoplastic disease is brought in with the use of the term "rectal shelf," which is usually applied to secondary malignant growths, primary in some other portion of the abdomen, implanted in the pelvis. The final course and description of this mass make it improbable that it was a malignant rectal shelf, and we otherwise have very little to support a neoplastic background. The patient had had no loss of weight or loss of strength, and the stools early in the examination

were negative for blood, so that I believe we can rule out cancer.

I believe we come down to the most frequent cause of an acute abdominal situation with inflammation and the development of pelvic abscess, and that is our old friend acute appendicitis. The severe epigastric pain was perfectly consistent with the onset of acute appendicitis. The sudden decrease in symptoms at the end of a few days was probably due to rupture of the appendix. At no time after the patient came into the hospital was she in any condition for exploration. I judge she was not operated on, and if the surgeons missed an opportunity to do her any good it was at the time that they might have drained a pelvic abscess. They described it so beautifully as a large mass filling the pelvis to the brim, fluctuant to the examining finger below. On this same day the x-ray film failed to show dilated loops of small bowel, which at times can give the impression of a pelvic abscess, therefore, it could not have been a dilated loop of small bowel that they were feeling by rectum.

The patient developed a Type 20 pneumonia. We have to take just a moment to consider the possibility that this woman had a so-called "idiopathic peritonitis" from the pneumococcus, resulting in this abscess. I mention this because it can occur in an adult. I have recently seen it in a man of thirty. The pneumonia was probably secondary and not primary, and I should be much surprised if we found in the end that she had an idiopathic peritonitis.

To come down to a final diagnosis, I shall put first, acute appendicitis with peritonitis and pelvic abscess, and second, diverticulitis of the sigmoid, with pelvic abscess. I think that we shall find that she did have gallstones, which were irrelevant and did not have anything to do with the story. Also she must have had pneumonia as a terminal disease.

DR BENJAMIN CASTLEMAN: Why did you rule out carcinoma of the sigmoid with pelvic abscess and perforation?

DR ALLEN: I did raise it as a possibility, and the thing that made me believe it probably was not a carcinoma was the lack of obstruction. This patient had mild ileus. I believe that if she had had a carcinoma of the sigmoid this woman would have had a large bowel obstruction if it was big enough and bad enough to produce a perforation, and in addition she should have had blood in the stools. It is also on this basis of lack of obstruction that I thought it was not diverticulitis of the sigmoid.

CLINICAL DIAGNOSES

Pelvic abscess, secondary to carcinoma of sigmoid with perforation?
 Diverticulitis of colon with abscess formation?
 Ovarian cyst?
 Intestinal obstruction.
 Terminal pneumonitis.

DR. ALLEN'S DIAGNOSES

Acute appendicitis, with peritonitis and pelvic abscess.
 Gallstones.
 Pneumonia.

ANATOMICAL DIAGNOSES

Acute appendicitis, with perforation.
 Pelvic abscess.
 Localized peritonitis.
 Bronchopneumonia, slight.
 Cholelithiasis.
 Arteriosclerosis, aortic and coronary.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: I am sorry we have none of the clinicians from the ward to discuss this case. The patient was admitted through the Emergency Ward, where she was seen by a surgeon. She was admitted on the medical service. The surgeons were called rather frequently in consultation throughout her hospital stay. At no time were they anxious to take her into their wards. The suspicions ran as Dr. Allen guessed—chiefly toward diverticulitis or cancer of the sigmoid, with secondary abscess formation.

At autopsy a large pelvic abscess was found, and floating free in its midst was the distal three quarters of the appendix. There was a wide open hole into the cecum, where its base had once been. There were also scattered pockets of pus between various intestinal coils, but no free fluid, no generalized peritonitis. It seemed probable from the autopsy findings that if she could ever have been got into condition to withstand any operation whatever, the abscess could have been drained through the rectum or vagina and she might have survived. The other findings at autopsy were not very striking. She had a considerable amount of arteriosclerosis, including some coronary sclerosis. The lungs were edematous and atelectatic and showed very little pneumonia, although there was a trace of it. She had three gallstones, each about 1 cm. in diameter.

DR. GORDON A. DONALDSON: She would have been drained if she had not developed a pulmonary infection. I believe the surgeons thought

she had a twisted ovarian cyst at that time and were reluctant to drain it because of the fact that the intestinal obstruction was decreasing.

CASE 27212

PRESENTATION OF CASE

A fifty-six-year-old Greco-American woman entered the hospital complaining of abdominal pain and vomiting. The history was obtained through an interpreter.

The patient was first seen in the Out Patient Department two and a half years before admission, at which time she complained of epigastric pain of four years' duration, which apparently occurred after meals. A Graham test showed a normally functioning gall bladder and no visible stones. One year later the patient again visited the Out Patient Department and stated that the attacks of epigastric pain were still present and appeared when her stomach was empty. It was worse in the morning, was not relieved by food, and was accompanied by gas and a feeling of "something jumping" in her stomach. The pain radiated through to the back and was almost severe enough to make her cry. Furthermore, the patient stated that she used laxatives frequently for constipation. On examination, there was tenderness in the left upper quadrant of the abdomen, and the liver was palpable one fingerbreadth below the costal margin; the examiner believed a hard mass was present below and posterior to the soft liver edge. The blood pressure was 160 systolic, 90 diastolic. A gastrointestinal series was negative, and examinations of the blood and urine were negative. The patient was seen a year later and six months before entry in regard to her tonsils, and again she complained of epigastric pain.

Two weeks before admission the patient began to suffer from sudden attacks of crampy abdominal pain accompanied by rumbling in the abdomen and the passage of gas by rectum. Vomiting of food just eaten appeared the next day. She remained in bed, and the symptoms increased so that the waves of pain occurred every few minutes and vomiting became almost constant. At the time of admission there had been no bowel movement for four days and not even the passage of gas for twenty-four hours.

At no time had blood been noticed in the vomitus or feces. The patient had lost 30 pounds in the past few years.

Eighteen years previously, a "large mass weighing 7½ pounds" had been removed from her abdomen. The family history was irrelevant.

On examination the patient was acutely ill and

suffering from spasms of severe abdominal pain, between which she seemed comfortable. The heart and lungs were normal; the blood pressure was 138 systolic, 70 diastolic. The abdomen was distended, and there were hyperperistalsis and ascites; borborygmus was associated with the pains. A surgical scar was present in the mid-line of the lower abdomen.

The temperature was 99°F., the pulse 98, and the respirations 25.

The urine was normal. The blood showed a red-cell count of 4,400,000 with a hemoglobin of 85 per cent, and white-cell count of 11,450. The blood Hinton reaction was negative.

A flat abdominal film showed several gas-filled loops of small intestine in the left upper quadrant. There was no evidence of cecal dilatation. A barium enema revealed no abnormality.

A laparotomy was performed on the day of admission. A small amount of free fluid was present in the abdomen, and innumerable implants of various sizes were seen on the small and large intestines and mesentery. The uterus did not appear to be enlarged, but it was surrounded by a mass of nodules. The entire small bowel was greatly dilated and thickened, as if by long-standing partial obstruction. The omentum lay in the upper abdomen and was adherent to the liver, which could not be palpated, but there were numerous nodules in the region. Owing to the extent of the disease, it was considered unwise to do a palliative bowel drainage. A biopsy specimen taken from the anterior peritoneum showed chronic inflammation.

Postoperatively the patient improved; there was no vomiting, and the bowel movements were satisfactory. The temperature varied between 99 and 103°F., and the white-cell count averaged 14,000. Gradually, however, abdominal discomfort returned, and a flat plate of the abdomen nine days postoperatively showed an unusually large amount of barium in the colon from the previous enema. Most of the barium lay in the right half of the colon, but it was also present in the descending colon, sigmoid and rectum. Markedly dilated loops of small intestine were seen in the mid-abdomen and upper abdomen. The following day another operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. GRANTLEY W. TAYLOR: I think we had better start with the x-ray examination.

DR. JAMES R. LINGLEY: This is the first abdominal film taken, showing gas-filled loops of dilated small bowel, forming a stepladder pattern in the left side of the abdomen. This finding is

constant in the succeeding examinations. There is possibly a little increase in density, suggesting a mass in the mid-lower abdomen. There also appears to be an area of narrowing in the upper sigmoid, which from the films might either originate in the bowel or represent involvement of the bowel from without.

DR. TAYLOR: We are concerned with a patient with a long-standing history of difficulty, chiefly referable to her gastrointestinal tract and upper abdomen, who suddenly developed an acute episode in the course of six days. Shortly before admission to the hospital, she had begun to have some evidence of weight loss. The original complaints were suggestive enough of gall-bladder disease to warrant investigation. But the Graham test showed normal function. It seems to me that that justifies us, even some years after the x-ray studies, in ruling out the gall bladder as having been responsible for her symptoms. There is some relation of the upper abdominal pain to the stomach, perhaps, in that the pain was more prominent when the stomach was empty. The pain radiated through to the back; I do not believe we can make much capital out of that at the present time. The other fact about the history is the removal of a tumor eighteen years before—a large mass weighing 7½ pounds. That was at the age of thirty-eight. It would have been of interest to know whether she had had normal menstruation following that removal. I think that should have been included in the history. At the time of laparotomy, no reference was made as to whether or not the ovaries were observed, or if so, what they looked like.

The patient came in quite obviously suffering from an acute obstruction, which the flat films bear out. It is of interest that there was no gas in the cecum, and it is reasonable to say that the diagnosis was certainly acute obstruction of the small intestine, with no obvious involvement of the colon. At examination, the patient was acutely ill. She had been obstructed for two weeks, and had been completely obstructed for four days, suffering from spasms of severe pain, between which she seemed comfortable. The abdomen was distended. Ascites and borborygmus were present with the pain. I suppose by ascites they mean shifting dullness. I do not consider ascites to be observable on physical examination; the evidences of it may be. The blood picture is interesting. The patient had had a long illness and an acute recent episode; yet the blood was quite normal. It may be that she was so dehydrated as a result of the emesis that the hemo-

globin represented a false level. A barium enema was described as showing no abnormality. Dr. Lingley points out an area suggesting a stenosing lesion high in the sigmoid, which I think we must keep in mind.

Laparotomy was performed at once, presumably for an acute obstruction. No mention is made of the use of a Miller-Abbott tube. Apparently the patient was so badly off that they thought that they had to operate at once, and perhaps start the tube at the same time. The laparotomy findings are very interesting. Free fluid was present, and innumerable implants of various sizes were seen. The small and large intestines and mesentery were all covered with them. One can recognize neoplastic implants in the abdomen, and sometimes numerous implants of various sizes are seen. The description does not convey very much to me. I should certainly have a clearer picture if I had seen them myself. If one had a case of tuberculous peritonitis, one could say that tubercles were implants and undoubtedly they would vary in size. One could describe the dissemination of echinococcal disease inside the abdomen as implants, and they would vary in size.

DR. TRACY B. MALLORY: Can you describe them a little more, Dr. Wallace?

DR. RICHARD H. WALLACE: They were grossly what you could call typical carcinomatous implants.

DR. TAYLOR: I presume so, and yet Dr. Wallace, who was concerned with the operation, presumably removed one of these from the anterior wall and it was proved not to be carcinomatous, so that he was certainly wrong in his interpretation of that one and he may have been wrong in his interpretation of all the rest of them.

I was about to say that in younger women you can see implants due to endometriosis—not so numerous as in this case, however. As I have previously mentioned, nothing is said about the ovaries. The uterus is described as not enlarged but surrounded by a mass of nodules. Were the ovaries there, or were they not seen because of the massive nodules? A tremendously dilated small bowel was found, but nothing is said about whether the colon also participated in this process or whether there was any collapse of the small bowel, any sharp transition.

If most of us were confronted with this situation, I believe we should have done exactly what Dr. Wallace did, that is, take a biopsy specimen and close up the abdomen, with the idea that we were concerned with widely scattered neoplastic implants and probably with obstruction at no one

point but at several places. Then we should have been as surprised as he was probably to have a pathologist's report of chronic inflammation of the tissue removed at operation.

The interesting point postoperatively is that the patient began to have a swinging temperature and more elevation of the white-cell count than before. She developed abdominal distention again and had obstruction, and then they found out that most of the barium was present in the colon from the enema that had been given some six days previously. I dare say at that time they may have scrutinized with more care that region in the sigmoid and decided that there might be carcinoma overlooked at the original operation. At any rate, another operation was performed, I presume with the thought of trying to relieve the obstruction, which then seemed to be more localized.

I have mentioned the non-neoplastic conditions that occur and that account for widely disseminated implantation of disease in the abdomen, namely, echinococcal disease, tuberculosis and possibly endometriosis. I do not believe we have to consider them. We have Dr. Wallace's assurance, and we have a pathological report that tends to rule them out just as completely or more completely than it rules out carcinoma. If we are dealing with carcinomatous implants throughout the abdomen, we must try to find a primary focus for the disease. We get very little help from the record in regard to where that primary focus probably was. We go back to the tumor removed eighteen years before to raise the question of whether the patient had ovarian neoplasm. Removing one ovary and leaving the other behind is very likely to be followed eventually, perhaps not after so long an interval as this, with malignant degeneration in the latter and the dissemination of implants. That is a very attractive diagnosis, because I suppose widespread intra-abdominal carcinomatous implants are more often due to ovarian carcinoma than to any other type as we see these cases surgically. However, many other areas may give rise to that type of dissemination. If we rule out the ovary, we think at once of the gastrointestinal tract—stomach, colon or rectum—as likely to give rise to widespread implantation. A negative gastrointestinal series was reported a year and a half before, but I think a carcinoma of the stomach could develop and become widely dispersed within that period. A suggestive area in the sigmoid colon and the presence of intestinal obstruction when she came in justify the assumption of involvement of the sigmoid. A carcinoma of the pancreas or biliary tract might develop in the ab-

domen rather silently and might progress to this extent, without interfering with the patient's well-being until there was widespread metastasis, but one would expect to have jaundice or some other evidence of a neoplastic process before this time. That is, I should expect either or both to have had liver metastasis before this widespread peritoneal implantation took place.

I neglected to mention the cecum specifically, but we know that a great many cecal carcinomas metastasize. I shall not consider it, however, because most of the obstruction was confined to the small intestines, and no mention is made of any mass in the cecal area. The only evidence in favor of carcinoma lower in the large intestine is the stricture or stenosis in the sigmoid colon.

I believe that, in spite of the negative biopsy of one of these nodules, the process is disseminated carcinoma. I believe that the patient had a carcinoma of the ovary, with disseminated implantation rather than primary involvement of the gastrointestinal tract. The obstruction was due to extrinsic infiltration of the bowel by this carcinoma.

DR. WALLACE: I operated on this patient with a diagnosis of acute small-bowel obstruction and found what I considered at the time very widespread metastatic disease. I was unable to palpate the liver or the region of the stomach because the omentum was adherent and had walled off the whole upper abdomen; its underside was a solid mass of nodules. Another mass of implants in the region of the terminal ileum was apparently chiefly responsible for the obstruction. There was also narrowing of the sigmoid in the site that Dr. Lingley has pointed out. The whole transverse colon was involved in the same process. There was no normal bowel with which to do a reasonable short-circuit operation, since there were implants down to the upper rectum. The peritoneum of the pelvis and around the uterus was one solid mass of nodules, and no ovary or ovarian tissue could be identified. I did not see the second operation. The patient continued to have symptoms of obstruction, and after ten days there was no great change. It was finally decided that it might be worth while to try to short-circuit the ileum to the upper rectum; this procedure was carried out apparently with great difficulty. The patient was not relieved, gradually went downhill, and died. Another interesting thing is that at the second exploration another biopsy was reported as showing chronic inflammation, although I do not believe there was any question in the minds of those who saw the inside of the abdomen that this was metastatic disease.

CLINICAL DIAGNOSES

Carcinomatosis.
Small-bowel obstruction.

DR. TAYLOR'S DIAGNOSES

Carcinoma of ovary.
Peritoneal carcinomatosis.
Small-bowel obstruction.

ANATOMICAL DIAGNOSES

Scirrhus carcinoma of stomach, signet-ring type, with multiple peritoneal implantations.
Intestinal obstruction.

PATHOLOGICAL DISCUSSION

DR. MALLORY: I might say that we have never been able to find anything that we could identify as carcinoma in either of the two biopsy specimens. At the time of autopsy, it was just as obvious to us as it had been to the surgeons that the patient was suffering from generalized carcinomatosis. We did have some advantage over the surgeons, and we were able to demonstrate that both ovaries were present. What the 7-pound mass was, I do not know. We found no trace of it. It may well have been a pedunculated fibroid. The primary site of the tumor was in the stomach. The lesser curvature was shortened to 10 cm. and was diffusely infiltrated with scirrhus carcinoma. There were many spots of obstruction throughout the intestinal tract, all due to serosal implantations. The maximum point of obstruction was probably in the region of the ileocecal valve, but the points of obstruction were so numerous that any satisfactory surgical relief would have been out of the question.

DR. TAYLOR: I recently read a paper describing the minute details of abdominal implantation of carcinomatous cells in the serous surfaces. Apparently, the implant imbeds and sets up inflammatory reaction of severe degree, accompanied by the formation of new blood vessels and new lymphatics. Thus the early nodule consists almost entirely of inflammatory tissue, and the actual cancerous focus may be overlooked by paying too much attention to the infiltration.

DR. MALLORY: I think that is quite possible. This cancer was of the signet-ring type. These cells spread individually and widely. An occasional signet cell does not look very different from a monocyte, and single cells may be quite difficult or impossible to recognize.

MASSACHUSETTS COMMITTEE ON PUBLIC SAFETY

THE co-operation of Massachusetts physicians is essential if the work of the Massachusetts Committee on Public Safety is to be successful. It is hoped and urged that physicians in every community will help the committee in the difficult task of organizing civilian and medical preparedness, in accordance with the program briefly outlined in a letter appearing in this issue of the *Journal*.

NEUROPSYCHIATRIC DISORDERS AND THE SELECTIVE-SERVICE-BOARD PHYSICIAN

THE casualties of World War I were not accounted for only in the number of men killed

and physically injured. Under the strain of military service and warfare, thousands of men broke down nervously so as to be useless in the fighting forces, and a large percentage of these, as chronic mental or nervous invalids, have been cared for ever since at governmental expense.

If the occurrence of such casualties were in no way predictable, if the man who is destined to become shell-shocked were as much subject to the laws of chance as the man who is killed or physically injured in a certain engagement, the whole matter of nervous invalidism under conditions of war would have to be considered one of the inevitable contingencies and unpreventable circumstances of the abnormal situation.

Statistical data relevant to neuropsychiatric disorders that developed in the United States Army during the last war indicate, however, that in an arrestingly large percentage of such disorders there had been a history of nervous or mental instability or neurologic defect long before the men entered military service. As reported in an article in this issue of the *Journal*, 85 per cent of 50,000 patients with neuropsychiatric disorders that apparently developed during the term of service had had symptoms relating to the disorders for at least five years before the beginning of military service. Furthermore, of a total of 69,394 neuropsychiatric patients found in examination of 3,500,000 soldiers, 96 per cent had disabilities that did not arise in line of duty.

Such evidence is conclusive proof that so-called "shell shock" does not come out of the sky, hitting this man or that man unpredictably, as shell fragments or bullets do. The significance of the experience gained from the last war is, of course, that adequate neuropsychiatric examination of the men about to be inducted into service will probably in large measure eliminate those who may become a liability in the country's defense and who may become a drain on governmental funds for years to follow. The importance and commonsense necessity for alertness and awareness, on the part of the examining physicians, concerning signs of nervous instability, mental deficiency and neurologic disease in the men who are being examined cannot be too strongly emphasized.

Because of the haste created by the present national emergency, men are being inducted into the United States Army following a relatively superficial examination. As a rule, they do not see a specialist in neuropsychiatry until they arrive at the induction station, just prior to going to camp. The induction examinations are necessarily hurried, and their adequacy depends chiefly on the acuteness, clinical acumen and extent of readily usable knowledge of the individual neuropsychiatrist.

It is these circumstances that make the position of the examining physician for the local selective-service board so relatively important. If he has in mind not only the finding of physical disease but also personality reactions and evidence of neurotic or psychotic tendencies and of subaverage intelligence, he himself may see reason to reject the unsuited man. If he is not able to decide on the fitness of the candidate, he has recourse to the medical advisory board, which has the time and facilities necessary for thorough examination.

Expert skill is not required to make the local-board physician watchful for indications of handicapping neurotic traits or of low mental caliber. A few simple questions about emotional reactions and school and work records will at least suggest whether further investigation is advisable. It is a mistake for the physician to shy away from considering personality disorders because of the misconception that this field belongs only to specialists. Most doctors have had sufficient experience with human nature to entitle them to the privilege of questioning the intelligence or the stability of the people with whom they come in contact. No harm—quite the contrary—is done by questioning, especially when it occurs before the final rush of induction-board activities.

The matter of mental deficiency should be carefully considered. The often-expressed idea that physically husky morons make the best soldiers is a fallacy. As a matter of fact, 12 out of every 1000 men examined in draft and camp groups in the last war proved to be unfit as soldiers because of mental deficiency. The warfare of today is said to depend more than previously on indi-

vidual initiative and intelligent co-operation; if this is true, the mentally deficient constitute even more of a liability. It is to the credit of the Boston Area Induction Board that a psychometrist is included in its medical personnel; he is able to judge the intelligence levels in doubtful cases.

Unfortunately, there seem to be no effective measurements for the quick determination of a man's capacity to fulfill the vocational duties of a soldier, even though the man is emotionally sound and of average intelligence. However, the evidence is that a workable ideal will be more nearly attained if men who are known to have personality defects are eliminated rather than put to the test of being made soldiers.

THE BOSTON MEDICAL LIBRARY: A HISTORY OF PROGRESS

In this issue of the *Journal* are two reports on the Boston Medical Library. The first is the report presented by the retiring president, Dr. Lincoln Davis, for 1933 through 1940; the second is that of the librarian, Dr. Henry R. Viets, for 1940, showing the present state of the library. The former is of special interest to readers of the *Journal*, many of whom are members of the library, since it covers a period of eight years during which the library passed through a state of financial crisis, now at least partially adjusted through the devotion of its officers and by donations from generous friends. In 1933, with a steadily falling income from invested funds and with a reduction in the number of members using the library, in addition to the piling up of debts accumulated over a long period of time, it is little wonder that the new president advocated the most stringent economies to meet the situation. Many adjustments were made immediately, and others as the subsequent years passed. Slowly, order has been restored, so that in 1941 Dr. Davis leaves his office to a successor, Dr. David Cheever, with the library in a greatly improved state.

The librarian's report indicates the steady growth of the library and its increased usefulness to the community. Much material of enduring worth was added to the library during 1940. The money

out the production of any notable sputum, the eyes become sunken, the cheeks flushed, and the finger nails become curved and the fingers warm especially at the tips, in some cases the feet swell, there is no desire for food, and vesicles appear over the body

Hippocratic Succussion The pathognomonic significance of this sign in hydropneumothorax was unknown to the Father of Medicine and his school. The maneuver is described in several of the Hippocratic treatises. The quotation is from Book Two of the *Diseases* (Littre, 7:70, Kühn, 2:258, Fuchs, 2:438):

When fifteen days have elapsed from the onset, bathe the patient in hot water, place him on a firm seat, and let an assistant hold his hands while you, yourself, shake him by the shoulders so that you may hear on which side the sound of the disease may be perceived

ACUTE APPENDICITIS IN PREGNANCY, WITH A FATAL OUTCOME

A twenty three year-old para II was first seen when about ten weeks pregnant. Examination at that time showed a perfectly normal patient. The heart was not enlarged, there were no murmurs. The lungs were clear and resonant, there were no rales. The blood pressure was 120 systolic, 60 diastolic. The breasts and abdomen were normal. The uterus was in good anterior position.

Shortly after her first visit, the patient was again seen because of pain in the abdomen associated with nausea and vomiting. These symptoms were believed to be due to the pregnancy, and a diagnosis of an acute infection in the abdomen was not made until four days after onset. At that time she was sent to the hospital, where an operation was performed. There was no record of the temperature or white cell count. The patient died four days after the operation.

Autopsy revealed acute peritonitis, a gangrenous placenta in utero, bilateral acute salpingitis and an acute gangrenous appendix.

Comment This case illustrates that surgical complications occurring in pregnancy must be

diagnosed early and treated early. Pregnancy is no contraindication to operation. It is fair to assume that early operation would have prevented this fatality. Undoubtedly the salpingitis and the gangrenous placenta were secondary to the general peritonitis. Formerly, it was believed that the pregnant woman was immune to infections and certain other conditions that the nonpregnant patient might have. Of course this is untrue, and the maternal mortality statistics for Massachusetts for the years 1937, 1938 and 1939 show that there were 10, 13 and 5 deaths, respectively, due to acute surgical complications. Too often the knowledge that pregnancy exists obscures an underlying surgical condition. In the presence of an even slightly increased white cell count a temperature only moderately elevated and indefinite signs in the abdomen,—signs that do not make a specific diagnosis simple,—it is far better to explore than to delay too long. Acute appendicitis in pregnancy demands immediate surgery. Procrastination, as illustrated in this particular case, is apt to lead to a fatal result.

DEATHS

COPELAND—STANLEY E. COPELAND, M.D., of Worcester, died May 13. He was in his fortieth year.

Born in Worcester, Dr. Copeland graduated from Dartmouth College in 1925 and from Harvard Medical School in 1928. He was a member of the staffs of the Worcester City Hospital and Worcester Hahnemann Hospital. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and daughter, two brothers and a sister survive him.

MATZEK—NEIL C. MATZEK, M.D., of Belmont, died May 13. He was in his forty sixth year.

Born in Milwaukee, Dr. Matzek received his degree from Tufts College Medical School in 1921. Formerly associated with the staffs of the Waltham and Symmes Arlington hospitals, he was a member of the staff of the Cambridge hospital, the Massachusetts Medical Society and the American Medical Association.

His mother, his widow, two children, two brothers and a sister survive him.

MISCELLANY

NOTES

At a recent meeting of the American Association of Physicians held at Atlantic City, Dr. James Howard Means, Jackson Professor of Medicine, Harvard Medical School was elected president for the ensuing year.

Erratum In the May 8 issue of the *Journal* it was announced that Dr. Walter B. Cannon had been awarded the Friedewald Medal of the National Gastroenterological Association, the society sponsoring the award was the American Gastro-Enterological Association.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

CORRESPONDENCE

MASSACHUSETTS COMMITTEE
ON PUBLIC SAFETY

To the Editor: The urgency of the present international situation has greatly accelerated the work of the Massachusetts Committee on Public Safety. Early in April, the medical division of the Massachusetts Committee on Public Safety sent out to the three hundred and fifty-three communities of Massachusetts directions concerning what each community should try to do in the way of medical preparedness. Compressed for the purpose of this letter, it broke down the medical division's efforts into three parts.

The first was the establishment of first-aid posts, either stationary or mobile units, in sufficient number according to the size of the locality. These posts should have physicians, nurses, nurse attendants and orderlies for full twenty-four-hour duty. These posts should be equipped with bandages, splints and the necessary materials for the immediate care of injured and gassed civilians.

Secondly, a transportation system to take the injured person from the first-aid post to the hospital should be planned. This transportation may be by ambulance or by any available vehicle that is adaptable to the needs of the locality.

Finally, the hospitals serving each community—and in those communities with no hospital the nearest hospital must suffice—should be prepared to handle any type of injury imposed by enemy action. Supplies in addition to those ordinarily on hand in time of peace must be put by. The staffs of the hospitals should be organized for a twenty-four-hour period of duty, perhaps best broken down into day and night shifts. This involves not only the physicians, but the nurses, nurse attendants, orderlies, dietitians and all others serving the hospital. Dentists must be included in the personnel, both in the hospitals and in the first-aid posts. Where there is an insufficient number of trained nurses, attendant nurses should be trained in attendant nurses' schools or through the excellent system of the Red Cross.

Already, replies on questionnaires attached to the original letters are coming in, and the number of towns that have no doctors and of course no hospital is surprising. Such towns are grouping together with adjoining communities and are doing the best they can to organize in accordance with the principles suggested for adequate civilian preparedness.

We take no outspoken stand on the imminence of disaster, although it is fair to state that the predicament in which both France and Great Britain found themselves and the subsequent fate of most of the democracies that are now Nazi-dominated were in large part the result of failure to be prepared.

We ask that the physicians of every Massachusetts community go to their local defense committee, for one has been appointed in every community, and, if that defense committee has a medical program, urge the committee to correspond with the Massachusetts Committee on Public Safety and to take steps in line with the suggested preparations. Through the dissemination of this information, the citizens of Massachusetts may fully realize their responsibilities. It is only when everyone shares in these labors that we may be actively and properly prepared.

ELLIOTT C. CUTLER, *Chairman*
Medical Executive Committee

A NEUROPSYCHIATRIC EXAMINATION
IN FIVE MINUTES

To the Editor: Yielding reluctantly to the pressure of Dr. Solomon Aronoff of the local induction board to put through 40 candidates without too great an infringement of their rights and civil liberties, I found myself improvising the following routine, which may be of some interest to your readers.

The applicant remains standing on entering the examining room. A general observation is made, including an examination for ataxia, atrophy and fibrillary twitchings, and the Romberg test. He then extends his hands for notation of tremors, and tests for adiadochokinesis—rapid alternation of pronation and supination of forearms—to determine the integrity of the cerebellar pathways.

The candidate kneels on a chair for Achilles-tendon reflexes, which are usually more reliable than knee jerks for ascertaining the integrity of the posterior columns and pyramidal tracts.

He sits and extends his legs for knee jerks (lumbar cord), while the examiner asks, "How far did you go in school?" (Stating the question at this time affords sufficient relaxation to check the knee jerks, which are especially valuable when the ankle jerks have not been satisfactory.) A maximum of sixth grade (normally completed at eleven or twelve years) or less, without adequate excuse (illness, work and so forth) suggests intellectual retardation.

The tendon reflexes of the forearm (biceps, triceps and radials) to verify integrity of the thoracic and the lower cervical segments, as well as checking on the pyramidal tract and the peripheral nerves, are checked as the next question—"What have you been doing since you left school?"—is propounded.

The pupillary reflexes (optic and oculomotor nerves) are then observed. Tests for ocular co-ordination, ocular muscular paralysis or weakness (oculomotor, trochlear and abducens nerves), nystagmus and other anomalies are made without questions, since any interference usually prolongs the time required for their performance.

The facial, the motor division of the trigeminal and the hypoglossal cranial nerves are tested rapidly, the examiner himself making the appropriate movements in demonstration. Thus: "Let me see your teeth, whistle, wrinkle up your brow [the seventh nerve]; open your mouth wide [the motor division of the fifth nerve]; stick out your tongue [the twelfth nerve]."

Vision and hearing are examined by the eye, ear, nose and throat specialist; any sensory and gross neurologic complaints are easily elicited through the following questions.

How do you feel?

Do you eat well?

How do you sleep? (Sleep and digestion are impaired first in neurotic persons.)

How are your stomach and your bowels?

Are you taking any medicine?

Do you have any aches or pains?

Does anything bother you?

How do you get along with girls? (If married, . . . with your wife?)

How many jobs have you had?

What is the longest time that you have spent on any one job? (A large number of jobs in a very

short time may suggest simple schizophrenia or a psychopathic inadequacy.)

How do you feel about this induction?

How do you feel about the Army?

Do you think that Germany should win? (This is asked if answers to the previous two questions are unenthusiastic, suspiciously noncommittal or unfavorable.)

Additional questions and time, when indicated, are in order, and are encouraged by the chief medical officer—especially when intellectual retardation is suspected from a history of limited schooling or from stupid responses to instructions during the examination. Thus, during an additional five minutes or so spent with the two or three dull inductees who are likely to be discovered in a group of fifty candidates, the following psychometric tests can be made:

Repeat six digits forward (twelve year test, Stanford)

Repeat five digits reversed (twelve year test, Terman-Merrill)

Give an acceptable definition—not too technical—of the abstract words, 'constant', 'courage', 'chirity', 'defend' (Terman-Merrill)

Name some rivers, cities and mountains in Massachusetts (Fernald) (Spelling of 'Massachusetts' has proved to be too great a stumbling block!)

Similarities (eleven year test, Terman-Merrill) The question is asked "In what way are rose potato and tree alike?" The same question for knifeblade, penny, piece of wire, or wool, cotton and leather and for book, teacher and newspaper

The ball and field test (superior plan for thirteen year level, Terman-Merrill, twelve year level, old Stanford), if presented as the problem of locating an unexploded bomb in a large circular enclosure would doubtless be very valuable, if it were not too time consuming

The commonest positive findings are linguistic handicaps in recent immigrants, sympathetic overstimulation (lost hands, hyperactive tendon reflexes and hyperemia), intellectual retardation (noted in 3 to 5 per cent of the inductees, with about 2 or 3 per cent rejected on this account)

Despite my bias against even attempting any kind of neuropsychiatric examination in less than thirty minutes with a candidate, I am obliged to conclude after examining 100 men, that in the vast majority of cases it is possible to make a reasonably reliable estimate of the neuropsychiatric assets of a candidate within five minutes.

The routine has been modified somewhat in indications arranged and some examinations have required much more time than many of them, however, have actually required less than five minutes.

Dr. Aronoff has informed me that my experience has been shared by the other neuropsychiatrists who have been examining at this center and I have no doubt that this report will be news only to the general physician and not to those neuropsychiatrists who have not been faced with a similar challenge.

Greeting the applicant with a smile, and the correct pronunciation of his name (ask him if in doubt) in addition to passing the time of day (Good morning, Mr. X) does much to build up rapport, a handshake and Good luck, Mr. X, at the close of the interview have proved very valuable, inasmuch as a smiling candidate who leaves the examining room with a "Thanks Doc" has a better effect on the rest of the men waiting outside,

not to mention its psychotherapeutic value to the future soldier.

It is important to remember that the essential distinction between these and ordinary neuropsychiatric examinations is that the overwhelming majority of these inductees do not (except in rare cases) have any complaints for which a differential diagnosis would be indicated. For this reason well over 90 per cent of them give negative findings and can therefore be disposed of with considerable ease and promptness.

Finally, I have observed that my own fatigue, which was quite marked at the end of each of the first two sessions, has not been noticed since then, so that, although I consider forty examinations a day to be the maximum load, it is not impossible or too difficult to handle fifty in a four hour session.

CALVERT STEIN, MD

121 Chestnut Street
Springfield Massachusetts

REPORT OF MEETING

CUTTER LECTURE

A Cutter Lecture on Preventive Medicine was delivered at the Harvard Medical School on March 7 by Dr. Ernest W. Goodpasture, of Vanderbilt University. His subject was Intracellular Infection and Some of Its Possible Implications. At present there is much evidence in favor of the necessity of an interrelation of the living cell and virus for the propagation of the latter. This same dependence is now known to hold in regard to certain protozoa, and recently some bacteria have been demonstrated to need a living cell, whereas others benefit from this relation, especially in regard to invasion.

Before discussing the evidence for these latter statements, Dr. Goodpasture described the chick-embryo method of studying pathologic processes. The perpetuation of various bacteria on this medium and their growth in the characteristic tissue of the human disease were discussed. It has thus been found possible to reproduce certain phases of human diseases especially the hitherto unexplored incubation period, on this medium. It has also proved beneficial in studying portals of entry and of measuring the potency of immune serum, since the chick embryo contains no antibodies or complement. It was suggested by Dr. Goodpasture that the method will therefore give a clearer idea of the mechanism of chemotherapy and prove more practical than *in vitro* experiments for antibody titer, and possibly will afford a new classification of bacteria based on a bacteria-cell interrelation.

On this latter basis the speaker has tentatively arranged certain familiar bacteria into three groups: extracellular, facultative extracellular or intracellular and obligate intracellular organisms. In the first group are *Corynebacterium diphtheriae*, *Staphylococcus aureus*, pneumococcus and *Streptococcus haemolyticus*. Slides were shown to demonstrate the well known necrotic action of diphtheria toxin and the protection afforded by antitoxin through better phagocytosis, the early leukocytic and exudative reaction with fixation abscess in infections due to *Staph. aureus*, the early monocytic reaction against the streptococcus, which is inhibited by the elaborated toxin and thus allows invasion and the inhibition of the pneumococcus by intracellular life. Among the organisms capable of either type of existence were demonstrated *Str. viridans* and the meningococcus both of which penetrate and destroy in either environment. An organism from a case of human

CORRESPONDENCE

MASSACHUSETTS COMMITTEE
ON PUBLIC SAFETY

To the Editor: The urgency of the present international situation has greatly accelerated the work of the Massachusetts Committee on Public Safety. Early in April, the medical division of the Massachusetts Committee on Public Safety sent out to the three hundred and fifty-three communities of Massachusetts directions concerning what each community should try to do in the way of medical preparedness. Compressed for the purpose of this letter, it broke down the medical division's efforts into three parts.

The first was the establishment of first-aid posts, either stationary or mobile units, in sufficient number according to the size of the locality. These posts should have physicians, nurses, nurse attendants and orderlies for full twenty-four-hour duty. These posts should be equipped with bandages, splints and the necessary materials for the immediate care of injured and gassed civilians.

Secondly, a transportation system to take the injured person from the first-aid post to the hospital should be planned. This transportation may be by ambulance or by any available vehicle that is adaptable to the needs of the locality.

Finally, the hospitals serving each community—and in those communities with no hospital the nearest hospital must suffice—should be prepared to handle any type of injury imposed by enemy action. Supplies in addition to those ordinarily on hand in time of peace must be put by. The staffs of the hospitals should be organized for a twenty-four-hour period of duty, perhaps best broken down into day and night shifts. This involves not only the physicians, but the nurses, nurse attendants, orderlies, dietitians and all others serving the hospital. Dentists must be included in the personnel, both in the hospitals and in the first-aid posts. Where there is an insufficient number of trained nurses, attendant nurses should be trained in attendant nurses' schools or through the excellent system of the Red Cross.

Already, replies on questionnaires attached to the original letters are coming in, and the number of towns that have no doctors and of course no hospital is surprising. Such towns are grouping together with adjoining communities and are doing the best they can to organize in accordance with the principles suggested for adequate civilian preparedness.

We take no outspoken stand on the imminence of disaster, although it is fair to state that the predicament in which both France and Great Britain found themselves and the subsequent fate of most of the democracies that are now Nazi-dominated were in large part the result of failure to be prepared.

We ask that the physicians of every Massachusetts community go to their local defense committee, for one has been appointed in every community, and, if that defense committee has a medical program, urge the committee to correspond with the Massachusetts Committee on Public Safety and to take steps in line with the suggested preparations. Through the dissemination of this information, the citizens of Massachusetts may fully realize their responsibilities. It is only when everyone shares in these labors that we may be actively and properly prepared.

ELLIOTT C. CUTLER, *Chairman*
Medical Executive Committee

A NEUROPSYCHIATRIC EXAMINATION
IN FIVE MINUTES

To the Editor: Yielding reluctantly to the pressure of Dr. Solomon Aronoff of the local induction board to put through 40 candidates without too great an infringement of their rights and civil liberties, I found myself improvising the following routine, which may be of some interest to your readers.

The applicant remains standing on entering the examining room. A general observation is made, including an examination for ataxia, atrophy and fibrillary twitchings, and the Romberg test. He then extends his hands for notation of tremors, and tests for adiadochokinesis—rapid alternation of pronation and supination of forearms—to determine the integrity of the cerebellar pathways.

The candidate kneels on a chair for Achilles-tendon reflexes, which are usually more reliable than knee jerks for ascertaining the integrity of the posterior columns and pyramidal tracts.

He sits and extends his legs for knee jerks (lumbar cord), while the examiner asks, "How far did you go in school?" (Stating the question at this time affords sufficient relaxation to check the knee jerks, which are especially valuable when the ankle jerks have not been satisfactory.) A maximum of sixth grade (normally completed at eleven or twelve years) or less, without adequate excuse (illness, work and so forth) suggests intellectual retardation.

The tendon reflexes of the forearm (biceps, triceps and radials) to verify integrity of the thoracic and the lower cervical segments, as well as checking on the pyramidal tract and the peripheral nerves, are checked as the next question—"What have you been doing since you left school?"—is propounded.

The pupillary reflexes (optic and oculomotor nerves) are then observed. Tests for ocular co-ordination, ocular muscular paralysis or weakness (oculomotor, trochlear and abducens nerves), nystagmus and other anomalies are made without questions, since any interference usually prolongs the time required for their performance.

The facial, the motor division of the trigeminal and the hypoglossal cranial nerves are tested rapidly, the examiner himself making the appropriate movements in demonstration. Thus: "Let me see your teeth; whistle, wrinkle up your brow [the seventh nerve]; open your mouth wide [the motor division of the fifth nerve]; stick out your tongue [the twelfth nerve]."

Vision and hearing are examined by the eye, ear, nose and throat specialist; any sensory and gross neurologic complaints are easily elicited through the following questions.

How do you feel?

Do you eat well?

How do you sleep? (Sleep and digestion are impaired first in neurotic persons.)

How are your stomach and your bowels?

Are you taking any medicine?

Do you have any aches or pains?

Does anything bother you?

How do you get along with girls? (If married, . . . with your wife?)

How many jobs have you had?

What is the longest time that you have spent on any one job? (A large number of jobs in a very

NEW ENGLAND HEART ASSOCIATION

The next meeting of the New England Heart Association will be held at the Evans Memorial Hospital on Monday, May 26, at 8:15 p.m.

PROGRAM

Presentation of cases. Dr. James M. Faulkner.
Studies on the Third Heart Sound. Dr. Norman H. Boyer.

Perforation of Interventricular Septum: Report of four cases Drs. G. Kenneth Mallory, William G. Peacher and Charles F. Branch.

The Nature of the Arterial Hypertension Produced by Administration of Angiotonin to Normal Subjects. Dr. Robert W. Wilkins.

Pericardiotomy for Purulent Pericarditis. Dr. John W. Strieder.

Cardiac Failure Due to Inter-capillary Glomerulosclerosis. Drs. Harold J. Jeghers and O. J. Wolleman.

Interested physicians and medical students are cordially invited to attend.

EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

The next examination for appointments as assistant surgeon (lieutenant, junior grade), United States Navy Medical Corps, will be held at all major Medical Department activities on August 11 to 15, inclusive. Applications for this examination must be received at the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., not later than July 15.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment, and graduates of a Class A medical school who have completed at least one year of intern training in a hospital accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association.

A circular of information listing physical and other requirements for appointment, subjects in which applicants are examined, application forms and other data pertaining to salary, allowances and so forth may be obtained from the Bureau of Medicine and Surgery on request.

An examination for appointment as acting assistant surgeon for intern training in naval hospitals accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association will be held at all major Medical Department activities on June 23 to 26, inclusive. Students in Class A medical schools who will complete their medical education this

year are eligible to apply for these appointments, and if successful will receive their appointments approximately after the date of the examinations. Students in Class A medical schools who will have completed their third year of medical education this year are eligible to take this examination, and if successful will receive their appointments on or about July 1, 1942, after they have completed their medical education.

Applicants for appointment as acting assistant surgeon for intern training must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment. Acting assistant surgeons are appointed for a period of eighteen months. After the appointee has served as an intern in a naval hospital for twelve months, he is eligible for and may take the examination for appointment as assistant surgeon.

A circular of information listing physical and other requirements for appointment as acting assistant surgeon, subjects in which applicants are examined, application forms and so forth may also be obtained from the Bureau of Medicine and Surgery on request.

Assistant surgeons and acting assistant surgeons for intern training are appointed in the rank of lieutenant (junior grade), Medical Corps, United States Navy. The pay and allowances for an officer of this rank total \$2699 per year if he has no dependents, and \$3158 per year if he is married or has dependents.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Mask of Sanity: An attempt to reinterpret the so-called psychopathic personality. By Hervey Cleckley, B.A. (Oxon.), M.D., professor of neuropsychiatry, University of Georgia School of Medicine, Augusta, Georgia. 8°, cloth, 298 pp. St. Louis: The C. V. Mosby Company, 1941. \$3.00.

Textbook of Medicine. By various authors. Edited by J. J. Conybeare, M.C., D.M. (Oxon.), F.R.C.P., physician to Guy's Hospital, London. Fifth edition. 8°, cloth, 1131 pp., with 24 illustrations and 31 x-ray plates. Baltimore: Williams and Wilkins Company, 1940. \$7.50.

The Avitaminoses: The chemical, clinical and pathological aspects of the vitamin deficiency diseases. By Walter H. Eddy, Ph.D., professor of physiological chemistry, Teachers College, Columbia University; and Gilbert Dalldorf, M.D., pathologist to the Grasslands and Northern Westchester hospitals, New York. Second edition. 8°, cloth, 519 pp., with 28 illustrations and 40 plates. Baltimore: Williams and Wilkins Company, 1941. \$4.50.

First Aid in Emergencies. By Eldridge L. Eliason, M.D., Sc.D., professor of surgery, University of Pennsylvania School of Medicine, professor of surgery, University of Pennsylvania Graduate School of Medicine, and surgeon, University of Pennsylvania, Presbyterian and Philadelphia General hospitals. Tenth edition, completely revised and reset. 16°, cloth, 260 pp., with 126 illustrations. Philadelphia: J. B. Lippincott Company, 1941. \$1.75.

The Essentials of Applied Medical Laboratory Technic: Details of how to build and conduct an office or small hospital laboratory at small cost. By J. M. Feder, M.D., director of laboratories and Allergic Service, Anderson County Hospital, Anderson, South Carolina. *Blood and Plasma Transfusion.* By John Elliott, Sc.D., pathologist, Rowan General Hospital, Salisbury, North Carolina. 4°, cloth, 241 pp., with 83 illustrations. Charlotte, N. C.: Charlotte Medical Press, 1940. \$5.00.

The Rockefeller Foundation: A review for 1940. By Raymond B. Fosdick, president of the Foundation. 8°, paper, 64 pp. New York: The Rockefeller Foundation, 1941.

The Heart in Pregnancy and the Childbearing Age. By Burton E. Hamilton, M.D., cardiologist, Boston Lying-in Hospital; and K. Jefferson Thomson, M.D., associate physician, Metropolitan Life Insurance Company Sanatorium, Mount McGregor, New York, and research associate in medicine, Albany Medical College; with a section entitled "Delivery and Obstetrical After-Care of Cardiacs," by Frederick C. Irving, M.D., professor of obstetrics, Harvard Medical School, and obstetrician-in-chief, Boston Lying-In Hospital. 8°, cloth, 402 pp., with 35 figures and

22 tables. Boston: Little, Brown and Company, 1941. \$5.00.

Criminal Youth and the Borstal System. By William Healy, M.D., and Benedict S. Alper, of the Judge Baker Guidance Center, Boston. 8°, cloth, 251 pp. New York: Commonwealth Fund, 1941. \$1.50.

BOOK REVIEWS

La maladie de Besnier-Boeck-Schaumann; ses manifestations cutanées, ganglionnaires, pulmonaires, osseuses, oculaires, glandulaires, viscérales, nasales, nerveuses. Une nouvelle grande réticulo-endothéliose. By L.-M. Pautrier. 4°, paper, 341 pp., with 105 illustrations. Paris: Masson et Cie. \$2.05.

In his preface, Professor Pautrier indicts the classic dermatologist in the following terms: "La dermatologie de collectionneur de timbres rares ou de papillons n'offre plus aucun intérêt. Loin de créer dix maladies nouvelles chaque année, il faudrait en supprimer tout autant. Nos méthodes trop longtemps purement visuelles ont raffiné et dissocié comme à plaisir. On discute gravement sur la présence ou l'absence de telle petite squame, ou de telle papule, ou de telle tendance à l'atrophie pour diviser, subdiviser, créer des types nouveaux, des formes anormales. Nous sommes ainsi arrivés à nous créer un vocabulaire invraisemblable, que rebute les débutants, perdus dans les règles de ce jeu compliqué et que, si nous n'y prenions garde, ferait bientôt de nous la risée des autres disciplines médicales."

Such words are most refreshing coming from a noted dermatologist and give hope that the days of descriptive dermatology are drawing to a close. In its history, sarcoid or Hutchinson-Boeck's disease is a good example of the danger of missing the woods because of the trees. The present monograph has successfully drawn together all that is known at the present time concerning this particular malady. It is fully illustrated, and the reproductions of photographs of skin lesions and of the x-ray changes are unusually good. The photomicrographs, however, are not, in general, so well portrayed.

Professor Pautrier has covered in a thorough fashion the literature on the subject, although it must be suspected that at times he has not read papers in the original, since authors' names are not infrequently misspelled—particularly authors writing in other than French journals. On the other hand, it is a monograph that should be on the reference shelf of every dermatologist and every internist concerned with this interesting but relatively uncommon condition.

Unfortunately, owing to world conditions, it is probable that few copies can be obtained in this country at present.

Diseases of the Urethra and Penis. By E. D'Arcy McCrea, M.D., M.Ch. (Dub.), F.R.C.S. (Ireland), F.R.C.S. (Eng.). 8°, cloth, 306 pp., with 181 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.50.

This book is an adequate account of the clinical aspects of diseases of the penis and urethra, accompanied by sufficient bibliographic references to bring the subject matter thoroughly up to date. Personal experiences of the author are only occasionally noted, so that the work represents almost wholly a compilation of material already in existence in most textbooks. This, together with the limitations of the subject itself, makes the book not worth an extensive review.

DANGERS OF RADIATION WITHOUT BIOPSY OF BRAIN TUMORS IN CHILDREN*

Report of a Case

FRANC D. INGRAHAM, M.D.,† AND JAMES B. CAMPBELL, M.D.‡

BOSTON

THE following case report is presented in the hope that similar disastrous results may be avoided. The patient had a good prognosis in other respects, but the resulting total and permanent blindness in this case is owing, we believe, to the fact that radiation was performed for over two years in the mistaken belief that the brain tumor was a medulloblastoma. The practice of radiation without biopsy and decompression has been carried out to a considerable extent in and about Boston (seldom elsewhere) since the presentation in 1935, and publication in 1936, of a rather convincing paper¹ advocating this method of attack. There is no doubt whatever that in many cases the diagnosis thus made is correct, that the patient is spared the ordeal of exploratory operation, and is as well off in the end. We are convinced, however, that even one case similar to that presented here is sufficient reason for discarding any method of treatment that makes such a result possible.

CASE REPORT

An 8-year-old girl entered the Children's Hospital with a complaint of headache, vomiting and unsteadiness of gait of more than 2 years' duration. Two months after the beginning of her illness, she entered another hospital complaining of headache and vomiting; examination showed poor reaction of the pupils to light and accommodation, hyperactive reflexes and a sustained right-ankle clonus. The history and signs suggested a mid line cerebellar tumor, and a diagnosis of medulloblastoma was made and x ray therapy recommended. The patient was given radiation as follows: at the beginning, 600 r to each side of the head; 4 months later, 600 r to these areas, 600 r to the posterior field directed at the cerebellum, 600 r to the cervical dorsal spine and 600 r to the dorsal lumbar spine, 6 months later,

600 r to each of the two lateral fields centered on the cerebellum; and 5 months later, 800 r to the same fields.

Four months after the completion of this treatment, the patient appeared in the Medical Out Patient Department of the Children's Hospital complaining of headache and vomiting, but the fact that she had been treated for a cerebellar tumor was not disclosed until her mother was questioned about the cause of the obvious alopecia. The signs at that time were characteristic of a cerebellar tumor; contact was made with the staff of the hospital where she was already under treatment, and she was returned to their care. Within a few days she received 800 r to the right and left cerebellar fields. A month later she received 600 r to the same fields and 600 r to the posterior cerebellar field. It was stated that "at first the patient responded rather well to the treatment, but after the last two series it appeared that she was becoming refractive, since there was little if any response, further treatment was therefore not given."

At the time of her last visit, the patient was found to have chronic papilledema, with secondary atrophy and distinct disturbance of co-ordination, so pronounced that she could hardly walk. She was given a very poor prognosis and told to return when necessary. A few days later, she was admitted to another hospital with the complaint of headache and vomiting. At this time, it was noticed that vision was very grossly impaired; the patient presented signs of high intracranial pressure, with cerebellar dysfunction. She was referred to the Children's Hospital, where she was admitted in a very poor condition, with very little vision remaining, and in almost complete prostration. A ventricular tap was done immediately after admission, and the fluid found to be under markedly increased pressure. Following this tap she improved considerably, and it was believed that she would tolerate a suboccipital exploration. This was carried out the day following admission, and a large cystic tumor was found extending into the mid line from the left cerebellar hemisphere. The cyst contained clear amber fluid such as is usually found in an astrocytoma. The cyst wall was fixed with Zenker's solution after evacuation, and the solid portion of the tumor removed. The patient made a satisfactory but rather slow convalescence, and was discharged from the hospital about 6 weeks after admission.

The pathological report was as follows:

On gross examination the specimen consists of nine fragments of soft, friable, pale yellow tissue of irregular

shape, ranging from 5 to 10 mm. in average diameter. Formalin section, done on one fragment, shows tissue to be consistent with that of an astrocytoma. The material is fixed in Zenker's fluid and formalin.

Fifteen sections were made and stained with eosin and methylene blue, phosphotungstic acid and hematoxylin, and aniline blue. Microscopically, the greater part of the sections consist of well-preserved, fairly homogeneous, neoplastic tissue. The predominant cell is stellate, with a round or oval vesicular nucleus and a small, deeply basophilic nucleolus. Two or three delicate fibrillar processes extend from a scanty cytoplasm. In some places the processes terminate along walls of small blood vessels. These fibrils, together with coarser fibers, comprising a loose intercellular substance, stain blue with phosphotungstic acid and hematoxylin. No mitoses are seen. The cells do not form rosettes, palisades or other characteristic configurations. There is moderate vascularization of the tumor, with small areas of epithelial proliferation and calcification in some of the vessels. Small areas of recent hemorrhage are scattered throughout.

Diagnosis: fibrillary astrocytoma.

With this case history, we should like to present some of the data from our series of intracranial tumors, which suggest that it is impossible to make

an accurate pathological diagnosis preoperatively, and that some of the prevalent ideas about intracranial tumors of children are incorrect.

In the first place, there is a general impression that medulloblastoma, which everyone agrees is radiosensitive and an almost hopeless surgical lesion, is the common intracranial tumor of childhood. In our series of 104 verified tumors (Table 1), there have been 21 children with medulloblastomas and 39 with astrocytomas. The patients were

all under fifteen years of age. In the older age groups, the incidence of medulloblastomas falls off rather rapidly. For the age group in question, this difference is not unique. The figures are very similar in Bailey, Buchanan and Bucy's series (30 astrocytomas, 13 medulloblastomas) and in Cushing's series (40 astrocytomas, 24 medulloblastomas).

The other important phase of the question is an analysis of histories of these patients, particularly with regard to duration of symptoms.

Figure 1 presents a contrast between the history as originally presented and as interpreted after special study in each case. One pair of columns represents one patient, the solid column representing the real duration of symptoms, the broken one the duration as originally presented by the family. Obviously, the majority of patients with astrocytomas present histories of symptoms of longer duration than those with medulloblastomas. So far as any individual case is concerned, it is quite impossible to determine the pathological diagnosis preoperatively.

Another item of importance is that some patients, particularly children with cerebral tumors, present apparently unmistakable cerebellar signs: 12 of our patients with supratentorial lesions had predominantly cerebellar signs. This is not an unusually high percentage in this age group; this pitfall was described with numerous examples by Bailey⁴ in 1924. Cushing⁵ had a striking example of this source of confusion in a small child with a large craniopharyngioma; in this case, the cerebellar signs were so striking that the surgeon who had previously treated the patient had tapped the cyst through a cerebellar approach. Certainly these patients would not be improved by radiation of the whole central nervous system, which is the routine treatment for medulloblastoma.

We realize that when radiation is started in the presumed medulloblastomas the plan is not to continue it unless there is a favorable response clinically. The case reported above illustrates very well how impossible it is to judge by the apparent response to the first ten days' treatment whether the diagnosis is correct. The record states that "at first the patient responded rather well to the treatment, but after the last two series it appeared that she was becoming refractive." The improvement was presumably owing to the fact that the coronal suture had separated widely at about that time. Even without the separation of the sutures, it is not uncommon to have unexplained spontaneous remissions in an otherwise steadily progressive course. It is not at all clear how such remissions can be distinguished from the beneficial effect of x-ray treatment, and there is therefore no

justification for depending on this improvement for a verification of diagnosis

In view of these several considerations, we consider a biopsy essential for an accurate diagnosis. Since a biopsy cannot be made safely without a decompression, a second important factor is taken care of—additional room, which should be pro-

vided with suspected brain tumors are given a trial course of x-ray therapy in less central and less expertly controlled clinics

It should also be noted that because of the local emphasis on this type of management medical students go through school with the impression that this procedure is generally accepted, whereas,

FIGURE 1 Differences in the Reported and Actual Duration of Symptoms

vided if radiation is indicated when an accurate histologic diagnosis has been made

We are not interested in emphasizing an error made by one surgeon or one clinic. As an advocate of this procedure has suggested, one mistake does not invalidate a method. This is certainly true, but the important point is that one cannot hope to have patients under better control or under more careful supervision than in the clinic where this patient was treated. Therefore, one must expect still more disastrous results when patients

actually, it is not generally accepted or approved throughout the United States

A STUDY OF THE SLIPPING-RIB-CARTILAGE SYNDROME*

JOHN F. HOLMES, M.D.†

MANCHESTER, NEW HAMPSHIRE

THE purpose of this paper is to call attention to an abnormal mobility and deformity of the anterior ends of the lower costal cartilages that cause painful symptoms, and to report cases observed over a period of twenty-seven years, emphasizing particularly persistent cases relieved by a simple operative procedure.

It should be understood that this particular syndrome has reference to the anterior ends of the rib cartilages and with the interchondral articulations, and is in no way concerned with the osteochondral junction of the anterior ends of the ribs, and that, barring anomalies, mistakes in numbering the ribs and exceptions, it has to do with the eighth, ninth and tenth rib cartilages only.

This symptom complex was first reported by Cyriax,¹ of London. He specifically mentions 3 cases, all treated expectantly. In 1922, Davies-Colley,² of London, under the original title, "Slipping Rib," reported 2 cases of displacement of the anterior end of the rib cartilage, which he had operated on by resection of the loosened cartilage with "complete relief of symptoms." From this time until 1924, 8 other cases by five authors³⁻⁷ were reported in the *British Medical Journal*. In 1931, Bisgard,⁸ of Chicago, referred to Davies-Colley's² article and other published cases, and reported 1 case, which he had operated on with cure. In the same year, Darby,⁹ of Vancouver, Washington, referred to Bisgard's publication and described a typical case of slipping rib cartilage that was also operated on by resection of the cartilage and followed by relief of pain.

This makes a total of 15 cases reported from 1919 to 1931, 8 of which were operated on by resection of the cartilage, with complete relief of symptoms.

Davies-Colley noted:

It is probably not a rare condition and is a trivial enough complaint in itself but it gives rise to most irksome symptoms. . . . In its [the pain's] position at the costal margin it resembles that due to so many deeper lesions of the abdomen and thorax, that I think it is quite likely that many cases occur in which such an apparently unimportant cause as a movable rib cartilage is unsuspected and the diagnosis missed.

Slipping rib cartilage is apparently of fairly common occurrence, and often produces irksome, in-

capacitating symptoms. It is diagnosed by physical examination, and cured by a simple operative procedure. As stated by Davies-Colley, "it is curious that it should receive no recognition in modern textbooks of surgery," and by Bisgard, "it has received but little attention in medical literature."

Because of failure to recognize this symptom syndrome, needless laparotomies have been performed, and prolonged suffering and incapacity

FIGURE 1. Sternocostal and Interchondral Articulations: Anterior view.¹¹ (Reproduced by permission of the publisher.)

from an easily curable condition are often permitted. Moreover, there does not appear to be any clear conception of the development of this deformity. These facts justify an attempt to secure a better understanding and more general recognition of this entity.

This loosening deformity involves the costochondral cartilages of the lower ribs, notably the eighth, ninth and tenth, either by displacement of fracture fragments or dislocation of the cartilage, or more often by curling of the end of the loosened

*One of the two essays awarded the Pray and Burnham prizes for 1940 by the trustees of the New Hampshire Medical Society.

†Surgeon, Elliot Hospital, Manchester, and Hillsborough General Hospital, Grasmere, New Hampshire.

cartilage, so that on respiration or motion the deformed end slips over or rubs against the inside of the rib above, with a click that is felt by the patient and, in some cases, with a severe and incapacitating pain.

Figure 1 shows the framework of the anterior chest wall; the anterior ends of the cartilages of the eighth, ninth and tenth ribs are usually attached to the one above, not by cartilaginous union, but by a fibrous hammock surrounding the interchondral synovial membranes of the interchondral articulations that lends to the desirable mobility of the anterior chest. At the same time, however, it has the instability characteristic of any joint, and hence the susceptibility to trauma.

Lilienthal¹⁰ states that "the weakest part of the thorax is along the costochondral line on either side." This is an important observation in the consideration of cause and effect.

ETIOLOGY

Abnormal mobility of these rib cartilage ends may begin acutely as a result of fracture or dislocation of the cartilage, or more often as a partial separation of the fibrous attachment. On the other hand, it may be the result of multiple injuries, which have stretched the fibrous attachments over a period of time—as from golfing or one-sided weight carrying. That trauma, direct or indirect, is the etiologic background seems reasonable.

Deformity of the loosened cartilage end may result from displacement of a fracture or dislocation, as will appear in one case reported, but is more often due to a *clac* upward of the loosened cartilage end—so it rises above the contiguous rib cartilage, *anically* slipping out and in over the superior *ulage* on certain movements of the chest, *us*, or by digital manipulation, with a *ch* pain that is diagnostic.

From a review of 33 cases, 15 reported and 18 of my own, it appears that slipping rib cartilage occurs more frequently from indirect than from direct trauma, there being 13 of the former and 6 of the latter; in 2 cases, both direct and indirect force were in evidence. Of the 12 other cases reported, no attempt was made to ascribe the cause, owing, I believe, to incomplete histories.

A sudden blow of the steering wheel of an automobile against the lower ribs is one method of direct injury. Indirectly it may be caused by sudden flexion, extension or twisting of the body; by repeated distortion of the body, as the one-sided weight carrying of an industrial worker; by a sudden pull on the arms, as in weight lifting or pushing; by repeated arm pulls, as in golfing; by forced compression or expansion of the chest,

as in childbirth or coughing; and by many other types of force.

In his original report of this entity, Cyriax¹ said:

Pain and tenderness produced by displacement of the anterior ends of the ribs or cartilages is doubtless due to irritation of the intercostal nerves in the vicinity, from which it may radiate to the posterior spinal nerves and thence to the thoracic or abdominal sympathetics.

Figure 2 shows the logic of this statement. According to Gray,¹¹ the intercostal nerves "pass for-

FIGURE 2 Diagram of the Course and Branches of a Typical Intercostal Nerve¹¹ (Reproduced by permission of the publisher)

ward in the intercostal spaces below the intercostal vessels." The description continues:

At the back of the chest they lie between the pleura and the posterior intercostal membranes but soon pierce the latter and run between these two planes of intercostal muscles as far as the middle of the rib. They then enter the substance of the *Intercostalis interni* and, running amidst their fibers as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and the *Transversus thoracis* muscle, pierce the *Intercostales interni*, the anterior intercostal membranes and *Pectoralis major*, and supply the integument of the front of the thorax over the mamma, forming the anterior cutaneous branches of the thorax.

Each nerve is connected with the adjoining ganglion of the sympathetic trunk by a gray and white *ramus communicans*.

Thus it is seen that the intercostal nerve lies very superficially on the inner surface of the anterior end of the rib and the rib cartilage, so that when the anterior end of the rib cartilage below becomes detached and deformed and slips up under the rib cartilage above, there is a strong

likelihood of nerve irritation. This probability is borne out by the fact that in every case reported, when the deformed cartilage is removed and clearance of the rib end established, the pain disappears immediately and permanently.

As cited by Cyriax,¹ and later by Davies-Colley,² the close association of the intercostal nerves with the sympathetic system accounts for frequent pain symptoms that suggest intra-abdominal or intrathoracic lesions, and has led to mistaken diagnosis.

Whether the synovial membranes of the interchondral joints that are involved in this slipping-rib-cartilage deformity contribute in any way to the pain manifested should be considered. So far, the pathological examinations of specimens obtained from these operations have revealed nothing of special interest.

Deformity of the loosened rib cartilage to produce the click and the accompanying pain develops secondarily, and hence may not be recognized as coming from the original injury. With this in mind, I believe a carefully taken history will, in all cases, show the original cause to be direct or indirect trauma.

DIAGNOSIS

Diagnosis of slipping rib cartilage is made from the complaint of pain, usually in the rib border, and by digital examination, with the patient relaxed and supine, with the knees flexed, in which position the abnormally movable rib cartilage, with its associated click and pain, can be demonstrated. Limitation of chest expansion as demonstrated by measurement is a suggestive diagnostic feature.¹² It is of the greatest importance in diagnosis to have in mind the possibility of this entity and a clear understanding of its development.

TREATMENT

Treatment of these cases as reported in the literature has largely consisted in excision of the rib cartilage involved, and has been followed by immediate and complete relief of symptoms.

I have treated the acute condition conservatively by adhesive strapping. Some of my patients have, in part at least, recovered with conservative treatment. Some of them have tolerated the pain and have preferred not to be operated on. The 8 patients whose symptoms have persisted and who have submitted to operation have been treated by excision of the rib cartilage or cartilages involved, which has resulted without exception in immediate and permanent cure.

Before operating on these patients, I have advised a two-day skin preparation, preceded by one or two hot-tub soaks. At operation I select a point

in the midaxillary line about three fingerbreadths above the umbilicus. With this point as a center, the incision is carried along and just above the rib border — 5 to 8 cm. Through the skin incision the operator's fingers are hooked under the rib border, and the offending cartilage is brought into the field. With the cartilage well supported by the fingers, a longitudinal incision is made through the muscles over the cartilage, exposing it. The soft tissues are pushed away, back to the junction of the rib, where the cartilage is disarticulated, and removed. It is quite brittle and may easily be broken in manipulation. This is an inconvenience and should be avoided. Careful digital examination, for abnormal mobility, is made of the adjacent cartilages. If any affected cartilage is found, it should be removed. In closure, the incised muscle is drawn in between the resected rib end and the rib above with plain catgut suture, and the end of the resected rib is buried in muscle. The skin is closed with interrupted sutures.

OPERATIVE RESULTS

Of the 16 patients with slipping rib cartilage operated on, — 8 in the literature and 8 of my own, — 8 were women and 8 were men. The ages ranged from sixteen to fifty-seven years. The condition occurred on the left in 7 cases, on the right in 8 and once bilaterally.

One rib was involved in 12 cases, two ribs in 2 cases, three ribs in 1 case and four ribs in 1 case.

In all cases there was an area of tenderness at the site of the lesion. In some cases the pain was sharp and incapacitating at times, being aggravated by twisting or bending the body, by deep inspiration or by motion of the arms. It radiated, in a different manner in each case, along the costal and sternal margins, to the back and into the abdomen. The patients frequently had a sensation of something slipping or giving way at the costal margin, coincident with a click and a pain. Some patients had the sensation of a "bunch" at the rib border, associated with pain. In a favorable position the patients were usually comfortable, but pain could be produced at any time by motion of the body or by manipulation of the loosened cartilage, so that the subjects were in constant fear of pain.

Following excision of the offending rib cartilage or cartilages, immediate and permanent cure was obtained in every case.

CASE REPORTS

CASE 1. D. C., a 20-year-old woman, was first seen at the Elliot Hospital, Manchester, New Hampshire, on March 3, 1912. She stated that she had received a direct injury to her left rib border, the result of a fall 3 months

previously, at which time she had suffered considerable pain. The chief symptom was pain in the left rib border on standing erect and on bending or twisting the body. The pain was occasional, with a slipping sensation. When lying down, the patient was comfortable.

Physical examination showed a deformity of the anterior end of the 10th left rib and cartilage.

At operation, the anterior end of the 10th left rib was found to be fractured. The anterior fragment, with its cartilage, was curled up under the costal border in such a way that it caused friction. The deformed end and the cartilage of the 10th left rib were excised. Ten days later, the patient was discharged well.

CASE 3 N. S., a 57-year-old laborer, was first seen on his admission to the Hillsborough General Hospital on May 22, 1934. The patient stated that his trouble had begun about 3 months previously, as a result of pulling on brush. He complained of pain and discomfort in the right rib border, particularly on trying to stand erect or on deep breathing.

The patient stood in a crouched position, his body bent forward and to the right. His general physical condition was good. There was localized tenderness, and a slipping sensation at the right rib border, associated with a click and manifestations of pain. This condition was diagnosed as fracture of the 8th, 9th and 10th rib cartilages, with deformity. X-ray examination of the chest was negative.

On May 26, at operation, the anterior ends of the 8th, 9th and 10th right rib cartilages were found loosened from their attachments and deformed. They were curled up under the rib borders and could be slipped back over the ribs above with a click. They were excised, and good clearance of the anterior rib ends was established.

The patient was immediately relieved. He made an uneventful recovery and was discharged on June 8.

In April, 1939, the patient reported that he had had no return of the pain in the right rib border. Examination showed the ends of the 8th, 9th and 10th right ribs to be smooth and nontender.

CASE 4 R. C., a 19-year-old bookkeeper, was first seen at my office on July 21, 1937. She stated that on June 21, when she was riding in the back seat of an automobile, the car ran into a tree and turned over. The patient was thrown to the top of the machine, and then fell to the floor. She was taken to a hospital, where examination showed "pain on pressure over the lower ribs on both sides." After 5 days she returned home, but complained of pain in the costal borders on both sides, pain in the back and limitation of abduction of the left leg.

The general physical condition was good. The patient stood in a stooped position, and walked with some difficulty. At the costal borders on both sides there was marked tenderness, and on manipulation the anterior ends of the 8th and 9th rib cartilages on both sides were found to be loosened. When these cartilages were displaced forward, a click, associated with severe pain, could be demonstrated. The patient's abdomen was symmetrical. There was marked limitation of abduction of the left leg and limitation of motion of the back.

On August 6, x-ray examination at the Elliot Hospital showed a fracture of the left pubic bone. The sternum and ribs were normal. On August 27, Dr. Ezra A. Jones applied a plaster jacket, immobilizing the pelvis and lower thorax.

While the patient wore the plaster cast, she made little complaint of pain in the rib borders, but when the cast

was removed and the back brace fitted, she had incapacitating and unendurable pain in the rib borders.

On January 4, 1938, she was admitted to the Elliot Hospital wearing a back brace. She complained of pain in the rib borders on both sides, aggravated by motion.

The patient stood in a crouched position. On digital examination of the costal borders, movable cartilages were felt, which slipped over the rib margins with a click and associated pain. She was nervous and depressed.

At operation on January 7, the 8th and 9th costal cartilages on either side were found detached at their anterior ends. The loosened ends were curled up under the rib borders. When the ends of the cartilages were manipulated, they came down over the rib borders with a click. The cartilages of the 8th and 9th ribs on both sides were excised. The following day, the patient stated that the pain in the lower ribs was gone. On January 21, she could stand erect and breathe freely, she was relieved of the old rib pain and was discharged from the hospital.

In April, 1939, the patient reported that, so far as her lower rib borders were concerned, she had no discomfort.

CASE 5 L. L., a 55-year-old teamster and woodchopper, was first seen at my office, on January 1, 1939. He stated that on December 31, 1937, while driving in a light wagon, he was run into by an automobile, and was thrown out onto the frozen ground, falling on his head and right shoulder. His shoulder was bruised, and his back was painful. On reaching home he found that he could not sit or stand erect. When he bent forward and inclined to the left, he was fairly comfortable, but when he stood erect, he felt a sharp pain at the center of his back, at about the level of the costal border, and along the left costal border. His chest and back were strapped, and he received medical treatment for 5 or 6 weeks. After 8 weeks, he returned to work but found that he could not load logs, which necessitated raising his arms high and brought his body into an extended position, causing severe pain. Two weeks later, he went to work as a chopper, and although he had some pain, he could work in a crouched position. He complained of severe pain in the back, about the level of the 12th thoracic vertebra and along the left costal border, particularly on deep breathing and when he tried to stand erect.

His general physical condition was good. Chest measurements were as follows: in repose, 37 1/4 inches, on expiration, 37 inches, and on inspiration, 38 inches. The patient stood and sat in a crouched position, with an inclination to the left. There was definite tenderness in the left lumbar region, with limitation of back motion in all directions: lateral motion to the right being most marked. The diagnosis was dislocation of the 12th left rib, or fracture of the transverse process of the 12th thoracic vertebra, and injury to the left chest.

X-ray examination of the dorsolumbar spine and lower ribs showed a moderate degree of arthritic change in the spine, but no evidence of other disease. Adhesive strapping was applied to the left chest.

On March 8, further examination showed that there was a slipping 9th left rib cartilage, which on motion caused a click and a pain.

On May 2, at the Elliot Hospital, an operation was performed. The 9th left rib cartilage was found detached from the rib above and curled up in the form of a hawk's bill, the anterior end of the cartilage resting on the inside of the rib above, so that when manipulated, the curled end of the rib cartilage came out over the rib above with a click. The deformed 9th left rib cartilage was excised. The

likelihood of nerve irritation. This probability is borne out by the fact that in every case reported, when the deformed cartilage is removed and clearance of the rib end established, the pain disappears immediately and permanently.

As cited by Cyriax,¹ and later by Davies-Colley,² the close association of the intercostal nerves with the sympathetic system accounts for frequent pain symptoms that suggest intra-abdominal or intrathoracic lesions, and has led to mistaken diagnosis.

Whether the synovial membranes of the interchondral joints that are involved in this slipping-rib-cartilage deformity contribute in any way to the pain manifested should be considered. So far, the pathological examinations of specimens obtained from these operations have revealed nothing of special interest.

Deformity of the loosened rib cartilage to produce the click and the accompanying pain develops secondarily, and hence may not be recognized as coming from the original injury. With this in mind, I believe a carefully taken history will, in all cases, show the original cause to be direct or indirect trauma.

DIAGNOSIS

Diagnosis of slipping rib cartilage is made from the complaint of pain, usually in the rib border, and by digital examination, with the patient relaxed and supine, with the knees flexed, in which position the abnormally movable rib cartilage, with its associated click and pain, can be demonstrated. Limitation of chest expansion as demonstrated by measurement is a suggestive diagnostic feature.¹² It is of the greatest importance in diagnosis to have in mind the possibility of this entity and a clear understanding of its development.

TREATMENT

Treatment of these cases as reported in the literature has largely consisted in excision of the rib cartilage involved, and has been followed by immediate and complete relief of symptoms.

I have treated the acute condition conservatively by adhesive strapping. Some of my patients have, in part at least, recovered with conservative treatment. Some of them have tolerated the pain and have preferred not to be operated on. The 8 patients whose symptoms have persisted and who have submitted to operation have been treated by excision of the rib cartilage or cartilages involved, which has resulted without exception in immediate and permanent cure.

CASE REPORTS

CASE 1. D. C., a 20-year-old woman, was first seen at the Elliot Hospital, Manchester, New Hampshire, on March 3, 1912. She stated that she had received a direct injury to her left rib border, the result of a fall 3 months

THE PROLONGED USE OF ENTERIC-COATED TABLETS OF THEOBROMINE SODIUM ACETATE IN THE TREATMENT OF EDEMA AND ANGINA PECTORIS*

JOSEPH E F RISEMAN, MD,[†] AND HARRY LINENTHAL, MD[‡]

BOSTON

THE use of xanthines in the treatment of edema has decreased greatly since the introduction of mercurial diuretics. The comparative popularity of mercurials is due not only to their superior diuretic action but also to the absence of the severe gastric distress that frequently attends the use of theobromine and theophylline derivatives. The mercurial diuretics possess disadvantages, however; they must be given intravenously, intramuscularly or rectally, great care must be exercised to prevent sloughing or thrombosis, and their administration to patients with renal damage is not without danger. There are therefore many cases in which an effective oral diuretic would be of value either as an adjunct or in place of a mercurial diuretic.

Theobromine and theophylline sodium acetate have been shown to be efficient xanthines in the treatment of angina pectoris.^{1,2} All xanthines, however, cause nausea and heartburn when given in large doses.² The following case histories illustrate that these untoward gastric effects may be minimized by encasing the medication in a so-called "enteric coating," thus often permitting its prolonged use in amounts adequate to keep certain patients free from edema.

CASE REPORTS

CASE 1 N G, a 66-year-old man, with chronic suppurative pulmonary infection and frequent acute febrile episodes for over 30 years, showed fibrosis of the left lung, with traction of the mediastinum to that side. In 1923, he retired from active business. Hypertension was first noted in 1924, one year later, left nephrectomy was necessary because of renal calculi. Pathological examination of the removed kidney revealed "subacute interstitial nephritis." After 1930, he had numerous episodes of paroxysmal auricular fibrillation that were relieved by quinidine and digitalis. In 1934, the urine began to show moderately large traces of albumin and a relatively fixed specific gravity, thereafter the blood pressure ranged between 200/100 and 250/150. In 1935, a right hemiplegia was followed by almost complete recovery.

In November, 1937, peripheral edema and an enlarged tender liver were noted for the first time. The electrocardiogram showed marked left axis deviation, with notched

QRS waves in Leads I and 4 and inversion of the T waves in those leads. The nonprotein nitrogen of the blood was 44 mg per 100 cc.

Because of the renal lesion, it was inadvisable to restrict the fluid intake to less than 2000 cc. The edema failed to disappear, and the patient became drowsy and irritable. Aminophyllin (0.2 gm three times a day) and later theophylline calcium salicylate (0.26 gm three times daily) produced a satisfactory diuresis and a loss of all visible edema in 3 to 5 days. The patient became so nauseated, however, that it was necessary to discontinue the therapy, and the edema returned promptly. The administration of smaller doses was followed by the same gastric distress and a lessened diuretic effect. A commercially available enteric coated aminophyllin tablet (Byk) and also tablets of theophylline calcium salicylate coated with salol were used with the same results. Although potassium chloride was of some value, the patient could tolerate only approximately 0.5 gm a day, and the edema did not disappear entirely. Mercurin rectal suppositories were tried on two occasions but caused local irritation and little diuresis. Intravenous mercurials were avoided because of the evidence of damage in the remaining kidney.

About 8 weeks after the onset of the edema, intravenous aminophyllin (0.25 gm in 10 cc) was given every other day. Marked diuresis and loss of about 8 pounds resulted, but within 48 hours the swelling of the dependent parts regularly returned. After 3 weeks the dose had to be increased to produce diuresis, within 2 months the patient was receiving 10 gm (40 cc) of aminophyllin intravenously every other day, each dose was followed by diuresis and a loss of 3 to 5 pounds of weight, but in the course of the next 24 to 48 hours, the edema always reappeared and was associated with drowsiness and mental confusion. At no time did the intravenous xanthines cause gastric or cerebral irritation.

The effectiveness of aminophyllin intravenously suggested that if a drug of the xanthine series could be given by mouth without producing nausea, the necessity for repeated intravenous injections might be obviated. The problem was presented to several pharmaceutical houses. Several enteric coatings were prepared and tested, not only for their solubility in acid and alkaline solutions, but also for their value as a coating for theobromine sodium acetate when given to patients with angina pectoris. In March, 1938, a tablet of theobromine sodium acetate, enteric coated with cetyl alcohol, was made available and appeared to have the desired physical and chemical properties. Roentgenograms were taken after administering by mouth tablets of barium sulfate coated with cetyl alcohol. The tablets passed through the stomach intact and disintegrated in the small intestine. With catharsis or diarrhea, the tablets passed through the intestinal tract intact. From four to eight 0.5 gm tablets of theobromine sodium acetate, enteric coated in this manner, were administered to patients with angina pectoris and normal laboratory workers in

*From the Medical Research Laboratories and the Medical Service, Beth Israel Hospital, the Department of Medicine, Harvard Medical School, and the Department of Medicine, Tufts College Medical School.

[‡]Professor of Clinical Medicine, Tufts College Medical School, physician and chief of Beth Israel Hospital.

single doses without gastric distress, and with no demonstrable weight loss or diuresis.

On the basis of these findings, the patient was given the enteric-coated tablets of theobromine sodium acetate by mouth in doses of 0.5 gm. three times daily. Four hours after the first tablet was given, diuresis began; after approximately 10 days, all visible edema had disappeared, the patient became mentally clear and less drowsy and no further intravenous medication was needed. From the onset of this medication until death 3 months later, the patient was free of visible edema, with the exception of one experimental period when the medication was stopped for a few days and the edema promptly returned. Death was due to an exacerbation of the pulmonary condition, with fever, and uremic coma.

Comment. This patient with chronic suppurative pulmonary disease, hypertension and congestive heart failure, had nephritis of the one remaining kidney. The administration of a diuretic by mouth was indicated, but the available preparations caused marked gastric distress. An enteric-coated tablet of theobromine sodium acetate was developed and tested both in the laboratory and on patients. From the time this preparation was first administered to the time of death no additional diuretic therapy was necessary.

CASE 2. Mrs. R. H., a 63-year-old woman, had a cerebrovascular accident in 1930, followed 3 months later by myocardial infarction. She recovered from both episodes and, despite the onset of auricular fibrillation in 1931, was able to carry on her household duties for over 6 years. Late in December, 1938, she was sent to the Beth Israel Hospital because of dyspnea on exertion, easy fatigability and dependent edema, all of 15 months' duration. For several weeks she had experienced attacks of paroxysmal nocturnal dyspnea, and for about 1 week had had considerable nausea and vomiting.

Physical examination showed moderate cardiac enlargement, a rough apical systolic murmur, completely irregular rhythm, a blood pressure of 210/110, a tender liver edge at the level of the umbilicus, rales at both bases of the lungs, signs of free fluid in the right chest cavity and pitting edema of moderate degree up to the knees. Laboratory data, including urine examination, blood counts and smears, blood nonprotein nitrogen, serum icterus index and blood serological tests, revealed no relevant facts. The electrocardiogram showed auricular fibrillation and depression of the ST segments in Leads 1 and 2, with partial inversion of the T waves in all leads.

During 38 days in the hospital the blood pressure fell to 160/90, and the signs and symptoms of congestive failure diminished markedly. The maintenance dose of digitalis was found to be 0.2 to 0.3 gm. daily. On the 4th day 750 cc. of fluid was removed from the right chest. Neither aminophyllin intravenously nor potassium chloride by mouth was of value as a diuretic. A mercurial diuretic (Mercupurin, 2 cc.) was administered intravenously on four occasions and by rectal suppository six times. Each treatment was followed by an increase in the urinary output from 500 to 1500 cc. and an improvement in comfort; however, pitting edema, rales and dyspnea became evident again within a few days.

Following discharge it was necessary to administer mercurial diuretics intravenously every 5 to 7 days. Late in March, 1939, enteric-coated theobromine sodium acetate therapy was begun (0.5 gm. four times daily). For the next 4 weeks no additional diuretics were necessary, and the patient remained free of edema. Her family physician then discontinued the xanthine therapy and resorted to

intravenous diuretics, but the signs and symptoms of congestive failure returned. When enteric-coated tablets of theobromine sodium acetate were again administered, intravenous mercurials became necessary only about once in 4 or 5 weeks. Three months later the patient died, a few days after another cerebrovascular accident.

Comment. This patient with arteriosclerotic heart disease, auricular fibrillation and congestive failure required intravenous mercurial diuretics every 6 to 7 days. Following the administration of enteric-coated tablets of theobromine sodium acetate, the intravenous therapy was unnecessary for weeks at a time. Cessation of the xanthine therapy resulted in reappearance of the signs and symptoms of congestive failure, only to be favorably affected by readministration of the drug.

CASE 3. N. B., a 51-year-old tailor with mild diabetes mellitus, had suffered from attacks of substernal and cordial pain that occurred on the slightest exertion, emotion from two to eight times daily and usually "2 minutes." These attacks were relieved by rest, nitroglycerin and were more frequent during the winter. He had been confined to bed for several weeks on occasions because of prolonged attacks.

Examination showed a short, stocky and exceedingly apprehensive man. There were peripheral and arteriosclerosis and pulmonary emphysema; the blood pressure was 130/85. An electrocardiogram and a 7-foot plate of the heart were normal.

When first seen in the clinic on November 4, 1938, the patient was receiving digitalis and was complaining of constant oppression, relieved slightly by nitroglycerin. Digitalis was omitted after 1 month of observation; the constant pain disappeared, but he experienced four to eight attacks daily. During the course of the next 16 months, different medicinal therapeutic measures were used, but none were effective except theobromine sodium acetate (0.5 gm.) and quinidine sulfate (0.3 gm.), which resulted in moderate improvement clinically (one to three attacks a day) and a slight increase in exercise tolerance, as measured under standardized conditions. On May 4, 1939, enteric-coated theobromine sodium acetate (1.0 gm. four times daily) was prescribed, with an additional dose (0.5 gm.) of the uncoated medication in the morning. On this regime the patient could walk farther, and the attacks were less numerous (two to three a week); the exercise tolerance increased. Each time tablets of lactose or sodium bicarbonate of similar appearance were administered, he experienced eight to ten attacks daily, and his exercise tolerance decreased. Each time 1 gm. of theobromine sodium acetate was administered, four times daily, definite improvement resulted. Larger doses (2 gm. four times daily) resulted in nausea and diarrhea and made it necessary to decrease the dosage of the drug.

Advantages of Xanthine Therapy

These cases illustrate the effectiveness of diuretics given orally in treating cardiac or renal edema. This concept is not novel, but the method has not been of maximum practical value because of the frequency of nausea and heartburn following their ingestion in adequate doses. During the last two years several effective enteric-coated preparations of theobromine and theophylline sodium acetate have become available commercially, and it is no longer necessary to rely on chemical houses

for a special supply of these drugs. In our experience the enteric coated theobromine sodium acetate marketed by Brewer and Company, Incorporated, and by E. R. Squibb and Sons and the theophylline sodium acetate marketed by the Upjohn Company, although covered with different enteric coatings, are effective diuretics that can be given by mouth in adequate dosage (one tablet four times daily) over long periods without gastric distress. We have found them of value in cardiac edema both with and without valvular damage or abnormal rhythm, and irrespective of whether the heart disease is of rheumatic, hypertensive or arteriosclerotic origin. We have had no experience with their use in syphilitic heart disease or cor pulmonale. Their greatest value has been in patients who required frequently repeated intravenous injections of mercurial diuretics. In such cases intravenous therapy was frequently unnecessary. Not all patients respond to this therapy, but the advantages of administering the xanthines by mouth make a trial advisable.

Disadvantages of Xanthine Therapy

The enteric-coated tablets are not so effective as the intravenous mercurials for the removal of accumulations of large amounts of edema fluid. Doses of 2 to 3 gm. of theobromine sodium acetate have been administered four times daily for two or three days to several patients with marked edema. Although these doses were usually well tolerated, the diuretic response was not satisfactory, and the intravenous mercurials had to be invoked to eliminate the residual edema.

It has been suggested that the gastric distress which may follow the use of the xanthines is due mainly to a central rather than a local action. This does not seem to be true, for patients who cannot tolerate small doses of the uncoated drug by mouth may take large doses of the enteric coated tablets orally without distress and with excellent therapeutic response; furthermore, large doses of aminophyllin can be given intravenously without gastric distress (Case 1).

The possibility of cerebral stimulation following the prolonged use of the xanthines has been another objection to their use. The close chemical relation of theobromine and theophylline to caffeine is probably responsible for this concept. We have administered 0.5 gm. of the enteric-coated theobromine sodium acetate 4 times a day for months to more than 100 patients with angina pectoris without observing a single case of nervousness, irritability or sleeplessness or any other evidence of cerebral irritation or stimulation.

Use in Angina Pectoris

Not all patients with angina pectoris respond to the sodium acetate derivatives of theobromine or theophylline, but it is apparent that they are of value in approximately half the cases. That the effect of the medication is not entirely psychological is shown by the increased amount of work that patients can do after the administration of the drug, and also by the fact that these drugs prevent the electrocardiographic changes that would otherwise occur during exertion.³

Adequate dosage is of the utmost importance. Unless the purines are given frequently in sufficiently large amounts and over long periods, the optimum therapeutic results will not be obtained. It has been found that the optimum dosage is usually the maximum amount that can be administered without inducing nausea.² The dose that has been found to be satisfactory for most patients was 0.5 gm. of theobromine sodium acetate or 0.2 gm. of theophylline sodium acetate given four times daily—before meals and before retiring. Most patients fail to derive benefit from smaller amounts. An occasional patient who does not respond to the usual dose may derive benefit from two or even three times this dose (Case 3). Some patients find the tablet of theobromine sodium acetate too large to swallow with ease, and a few experience slight gastric distress despite the enteric coating. In such cases it is advisable to give the medication more frequently but in smaller amounts (0.25 gm. five or six times daily).

The enteric coating delays absorption for four to six hours. It is obvious, therefore, that it is the medication taken before retiring that is effective in the early morning, and that a dose taken on arising may be of no value in preventing attacks of angina pectoris during the forenoon. Some patients continue to have pain during the morning despite this late evening dose. In such cases the administration of 0.25 or 0.5 gm. of uncoated theobromine sodium acetate on arising, in addition to the coated tablet, is of value. If the patient is free of pain during sleep, the dose after supper may be omitted.

So far as we know, the medication must be continued indefinitely in most cases, and any interruption of medication will usually be followed by a return of symptoms within a few weeks. An occasional patient, however, may be free from pain for several months after taking the medication for a few weeks. There is little evidence of development of a tolerance to the drug. Occasionally the use of the medication is followed by a period of freedom from pain, with later reappearance of discomfort despite continuation of medication. In

some cases, evidence of progression of the disease may be found, such as electrocardiographic changes and increased sedimentation rate.

Use in Other Cardiac Conditions

The success achieved with the use of theobromine sodium acetate in angina pectoris and edema has led us to employ the drug in other conditions, especially arteriosclerotic heart disease and hypertension, for according to recent investigations,³ the drug causes coronary dilatation, and therefore better myocardial nutrition. We have never observed any appreciable lowering of the blood pressure following this medication. Some patients with cardiac asthma, however, appeared to have less frequent attacks following administration of the drug.

CONCLUSIONS

Enteric-coated tablets of theobromine sodium acetate and theophylline sodium acetate are now available, which make it possible to give therapeutically adequate doses of these drugs over long

periods. By this means, the necessity of intravenous administration of diuretics may be obviated or decreased in certain patients with heart disease or nephritis, and the frequency and severity of attacks of angina pectoris may be diminished. When the drugs have been given continuously for a long time, no untoward effects have been observed except for occasional slight gastric discomfort. The optimum dosage for most patients appears to be 0.5 gm. of enteric-coated theobromine sodium acetate, or 0.2 gm. of enteric-coated theophylline sodium acetate, given four times daily, before meals and before retiring. Adequate dosage is necessary; in angina pectoris it is especially important to administer a dose of the medication before retiring.

DIAPHRAGMATIC ABNORMALITIES SECONDARY TO TUMORS*

A Roentgenologic Study

JOHN W. TURNER, M.D.†

SPRINGFIELD, MASSACHUSETTS

THE exact status of the diaphragm in non-neoplastic diseases is often difficult to determine from the clinical findings alone. In recent years, various x-ray diagnostic procedures have provided helpful supplementary evidence. Since the symptoms produced by most diaphragmatic abnormalities are difficult to interpret, it is not surprising that these conditions may be easily overlooked among patients with malignant tumors and that, consequently, many complaints are dismissed on the basis of probable visceral metastases or the patient's poor general condition. Thorough investigation both by x-ray films and fluoroscopy is essential for the recognition of most diaphragmatic disorders. Thus it seems highly desirable to direct more attention to patients with tumors who present symptoms referable to the diaphragm.

In recent reviews and reports of primary diaphragmatic tumors,¹⁻³ malignant neoplasms are about twice as common as benign ones. Much more frequently, the diaphragm is secondarily in-

involved by metastases or by direct extension of a cancer primarily situated in the breast, lung, stomach or more remote organs. Most cases of secondary neoplastic invasion of the muscular structure of the diaphragm produce no striking symptoms, and attention is usually drawn to the site of the primary or of the skeletal and visceral metastases.

Moreover, changes in and adjacent to the diaphragm are not infrequent in patients with neoplastic disease — in addition to the primary and secondary diaphragmatic neoplasms mentioned above. Three separate entities seem worthy of further attention and are exemplified by the accompanying case reports.

SUBPHRENIC ABSCESS

Perforation of a tumor of the colon has been listed by Graham⁴ as an occasional cause of left subphrenic abscess, the more frequent causes being perforated peptic ulcer, post-partum infection, and the other conditions that produce a peritonitis. Although subphrenic abscesses are only 20 to

*From the Cancer Section, Westfield State Sanatorium, Massachusetts Department of Public Health.

†Radiologist, Westfield State Sanatorium; out-patient roentgenologist, Springfield Hospital.

25 per cent as common on the left as on the right in the average surgical practice,⁵ among tumor patients the opposite distribution seems to hold, with neoplastic perforation as the most frequent cause. The stomach seems fully as important a site for neoplastic perforation as the colon.

It has often been found that the appearance of an unexplained pleural effusion, with pleural thickening and suppurative pneumonitis, may provide a helpful clue to possible subphrenic disease. Pleural and pneumonic complications from subphrenic

may also lessen the severity of the process by simulating the effect of drainage. It seems evident that the neoplasms that are well differentiated and show less frequent ulceration are the least likely to result in perforation. Among the tumors that increase the probability of this occurrence, the lymphoma group must be included.

CASE 1. A 48-year-old undertaker entered with complaints of tiredness and abdominal pains for the previous 6 months. The pain was described as sharp epigastric discomfort with radiation to the left costal margin. A Sippy diet had been tried, with the result that the character of the pain changed only from sharp to dull. There had been a weight loss of 76 pounds. A productive cough had been present for 4 weeks.

A roentgenogram of the thorax (Fig. 1) revealed marked left basilar pleuritis and evidence of fluid accumulation. Barium examination of the upper gastrointestinal tract revealed a very large ulcer crater involving the proximal portion of the greater curvature of the stomach (Fig. 2). The barium flowed readily from the

FIGURE 1. Case 1.

FIGURE 2. Case 1.

A film showing an irregular carcinomatous ulcer of the proximal greater curvature of the stomach, with escape of barium into a subphrenic abscess.

intraperitoneal abscess, which occur in 22 to 50 per cent,^{6,7} and from extraperitoneal subphrenic suppuration of perirenal origin, which occur in 16.5 per cent,⁸ have been explained by the richness of the lymphatic supply, including extensive transphrenic communications. With fluoroscopic evidence of fixation of the affected dome of the diaphragm and the opportunity to visualize the barium-filled cardia of the stomach, early detection of subphrenic abscess is more certain. As compared with the same condition in patients without cancer, a contrast exists in the usually less severe illness seen in subphrenic abscesses that follow the slow perforation of a tumor, for the neoplastic tissue often contributes to the walling-off process. Maintenance of communication of the abscess cavity and a hollow viscus through the perforation,

depth of the ulcer crater into a large subphrenic abscess cavity. After a few weeks of supportive treatment the patient expired as a result of a carcinomatosis.

Comment. This case presented a characteristic clinical picture of ulcerating carcinomatous involvement of the proximal greater curvature. The passage of barium from the stomach into the abscess cavity added convincing evidence of the mechanism involved in arriving at the end result of basilar pleuritis, effusion and pneumonitis.

PHRENIC PARALYSIS

The reported causes of spontaneous phrenic paralysis are numerous, including compression by new growths and other masses, syphilis, diphtheria, scarlet fever, infantile paralysis, ascending paralysis and extensive mediastinal, basilar or generalized pleuritis.⁹ However, this complication is relatively infrequent among patients in a general hospital. On the other hand, among tumor patients neoplastic phrenic paralysis is more frequent than all other causes combined. The variation in the level of the diaphragmatic domes in normal persons is so great that by x-ray evidence alone the condition may remain unrecognized unless fluoroscopic observation for paradoxical excursion is conducted.

The presence of phrenic-nerve invasion by neoplastic tissue is observed with or without other intrathoracic disease; thus, from a carcinoma of the breast, or any other cancer causing extensive neoplastic lower cervical and medial supraclavicular nodes, one may see phrenic interruption, even in the absence of pulmonary or mediastinal metastases. Occasionally both the phrenic and recurrent laryngeal nerves are invaded, with paralysis of the vocal cord and the dome of the diaphragm on the same side as the mass of palpable medial supraclavicular and cervical nodes. Occasionally the phrenic nerve is invaded as it passes through the superior mediastinum,¹⁰ or along the middle mediastinum anterior to the hilar structures on each side or more distally between the pleura and pericardium. Thus it seems worth while to investigate any unexplained elevation of a diaphragmatic dome in a patient with cancer of the lung. One may assume that paralysis, if present, proves that a primary lung tumor has advanced beyond successful treatment by pneumonectomy, even though film evidence of such spread is lacking.

The return of function that occurs in cranial and other nerves after regression of the neoplasm from radiation therapy¹¹ also follows palliative application of x-ray for phrenic palsy. Frequently the dyspnea is quite distressing, even in the absence of any pulmonary involvement. It is surprising that return of motor function can occur in only a few weeks following radiation therapy. A recent case of sudden complete paralysis of the right sixth cranial nerve in a patient with widespread Hodgkin's disease disappeared in sixteen days after the first x-ray treatment. This was interpreted as indicating a compression of medullated fibers by neoplastic cells, rather than a complete division of such fibers by the neoplasm.

CASE 2. A 34-year-old paper-mill employee was admitted with complaints of dyspnea, cough, fatigue and weight loss of 8 months' duration. Examination, which included

x-ray studies and bronchoscopy, revealed a carcinoma simplex of bronchiogenic origin in the right lower lobe. A moderate elevation of the right dome of the diaphragm observed in the films (Fig. 3) was found on fluoroscopic study to be the result of complete phrenic-nerve paralysis. Hilar, mediastinal and supraclavicular nodes were enlarged. Palliative x-ray therapy caused regression of the thoracic disease, but there was a rapid decline in the patient's general condition, with terminal jaundice. At the last admission 3 months later, the icterus index was 90, and the serum van den Bergh revealed 10 mg. of bilirubin per 100 cc., direct reaction.

Post-mortem examination showed invasion of the right phrenic nerve from the medial right supraclavicular

FIGURE 3. Case 2.

A film showing elevation of the right dome of diaphragm from paralysis, intrathoracic changes from a carcinoma of the right lower lobe and metastases to the right hilus and mediastinum.

metastatic adenopathy. Pancreatic metastases caused obstruction to the bile duct. Metastases to the heart, duodenum, mesentery of small bowel, adrenal glands, kidneys, cerebrum, and cervical, mediastinal, abdominal and pelvic lymph nodes were observed.

Comment. In this case there was obvious post-mortem evidence of phrenic-nerve invasion. The site of invasion was in the medial supraclavicular region, rather than at a more distal level. Thus the absence of a pulmonary lesion, as in cancer of the breast, does not exclude the possibility of phrenic palsy. In fact, phrenic-nerve invasion by neoplastic tissue seems more frequent at the level of the medial supraclavicular lymph nodes than any other section. Although treatment did not accomplish regression with return of function, such an occurrence has been observed in other cases.

HIATUS HERNIA

As an occasional complication of large tumor masses or large accumulations of fluid within the abdomen, the formation of an epiphrenic gastric pouch by hiatus herniation deserves mention. Dur-

ing recent years symptoms referable to small gastric pouches above the diaphragm have received considerable attention and careful study. Evans and Bouslog¹ have reported its occurrence in pregnancy as a cause of pyrosis. Reid¹² has reported simulation of cardiac infarction by hiatus herniation, and a peptic ulcer in the lower esophagus may occasionally be traceable to hiatus herniation with regurgitation, according to Chamberlin.³

CASE 3 A 56-year old housewife entered the hospital complaining of abdominal discomfort of about 30 months duration. Originally these symptoms were very slight. An x-ray investigation at another hospital shortly after onset of the disturbance had demonstrated a oval 4 cm tumor, with persistent deformity of the greater curvature of the stomach near the junction of its middle and distal thirds. The symptoms were so slight that operation was declined.

When first seen at the Cancer Section of the West

FIGURE 4 Case 3

A film showing deformity and elongation of the stomach from fixation to a mass—a retroperitoneal hemangioendothelioma—along the greater curvature

field State Sanatorium, the patient had experienced persistence of symptoms. In addition substernal pain frequently occurred, especially when she was in the recumbent position. Physical examination revealed a large irregular mass extending down to the umbilicus. Cichexia, ascites and edema of the lower extremities were observed. X-ray studies revealed fixation of almost all the greater curvature to a very large mass (Fig 4). This mass was found to be separate from the liver and spleen. The adjacent gastric rugae were normal, that is, there was no fluoroscopic or film evidence that the tumor had involved the mucosa. The transverse colon and adjacent flexures were displaced downward and anteriorly (Fig 5). Ex-

ploratory pyelograms showed no urinary tract abnormality. Six months elapsed before the patient would consider hospitalization, although laparotomy was advised from the first.

Exploratory laparotomy revealed a large irregular cystic tumor about 18 by 22 by 10 cm. The main tumor mass arose in the region of the pancreas and projected into the lesser peritoneal sac. The mass was attached to structures about it distally to 3 cm below the level of the umbilicus and proximally to the liver and stomach.

Histologically the tissue was found to be typical of

FIGURE 5 Case 3

A film made during fluoroscopy to show the epiphrenic gastric pouch that resulted from hiatus herniation

hemangioendothelioma both by frozen and paraffin sections.

Comment The occurrence of a large cystic tumor and ascitic fluid in this case simulated the abdominal enlargement of late pregnancy. The hiatus hernia may be assumed to have been related to the consequent increased intraabdominal pressure. This assumption is verified by the lack of any such finding at the onset of symptoms, when an upper gastrointestinal examination was done prior to the time the tumor reached its final large size or ascites appeared. The frequency of abdominal enlargement from neoplastic disease, particularly ovarian tumors affords this type of increased intraabdominal pressure which may assert itself by herniation of the stomach through the esophageal hiatus.

CONCLUSIONS

More careful clinical and roentgenologic attention to the diaphragm in patients with neoplastic disease is advocated.

Lack of pathognomonic physical signs of subphrenic abscess, neoplastic phrenic paralysis and hiatus herniation in these patients calls for thorough investigation of symptoms referable to the diaphragm and adjacent structures.

Fluoroscopy, films during and after fluoroscopy and fluoroscopic visualization of the barium-filled cardia are of established value and in fact are often essential for the diagnosis of these complications.

CLINICAL NOTE

EMERGENCY TREATMENT OF TRAUMATIC EMPHYSEMA OF THE MEDIASTINUM

GERALD L. GAUDRAULT, M.D.,*

AND

DUNCAN M. CHALMERS, M.D.†

CONCORD, NEW HAMPSHIRE

A STUDY of the literature on traumatic emphysema of the mediastinum confirms the statement of Heuer¹ that "procedures directed to the mediastinum itself, with the idea of allowing the escape of air or to close the lesion from which the air is escaping, have not been numerous in the literature." He quotes Gatellier and Barbary² as reporting that 2 of their 3 patients died because lateral incisions under the clavicle did not permit satisfactory escape of the air. The third patient recovered following incision at the base of the neck, with separation of the pretracheal and peritracheal tissues. Heuer also states that Phocas and Apert³ performed artificial pneumothorax in some cases, with eventual recoveries.

The effect of air in the mediastinum is not always serious. Fortunately, in the greatest number of cases the symptoms are mild, and Nature takes care of them with no help from the surgeon. In a few cases, however, the effects are very serious. Concerning these, Heuer¹ states: "The heart, great vessels and trachea may be compressed or dislocated, giving rise to urgent symptoms. These are marked agitation and anxiety, cyanosis, tachy-

cardia, signs of suffocation, tumefaction of the base of the neck and a rapidly spreading emphysema." In such urgent cases the surgeon has to work fast to save the patient.

Babcock⁴ states that emphysema of the mediastinum may seriously upset respiration and circulation, but that subcutaneous emphysema usually disappears spontaneously in a few days. Warbasse and Smyth⁵ believe that emphysema occurring in connection with such wounds of the pleura usually requires no treatment; in most cases the air is absorbed, and if it should give distress, it may be liberated by incisions of the skin. DaCosta⁶ makes a similar statement: "Emphysema usually disappears, but if it does not, make many small incisions and employ pressure." Eliason⁷ admits that injury to the pleura and lung producing mediastinal emphysema may be the cause of death, but states that emphysema from this cause usually requires no treatment, disappearing in about ten days. Hertzer and Chesky⁸ also found that emphysema in the tissues is soon absorbed. Watkins⁹ and Stenbuck¹⁰ follow the opinion of the preceding men and agree that if left alone the air will be absorbed naturally without the aid of a suprasternal-notch incision; if active measures are contemplated, both recommend artificial pneumothorax as the method of choice. On the other hand, suprasternal-notch incision with applications of a suction cup, according to Lenormant,¹¹ is necessary in most cases.

All cases of emphysema of the mediastinum do not fall into the hands of surgeons of wide experience, and are not treated in large metropolitan hospitals. What if a serious case falls into the hands of a surgeon who has never seen one like it? It surely is too late to start looking for literature on the subject, since cases are extremely rare and, hence, difficult to find. He can only go

*Member of active staff, New Hampshire Memorial Hospital, and of associate staff, Margaret Pillsbury General Hospital.

†Formerly resident, Pembroke Sanatorium, Concord, New Hampshire.

ahead immediately and do those things that, according to his senses, seem to be called for

The following case is reported, not to present a masterpiece in chest surgery but to be of service, if possible, to someone who might be called on to save a patient's life under similar circumstances

CASE REPORT

A 63-year-old man fell off a scaffold and landed on his right thoracic region. One of us (D M C.) removed the patient to the hospital immediately.

Examination revealed a massive accumulation of subcutaneous air extending over the upper thorax, supraclavicular region, face and upper extremities. Perspiration was profuse. The temperature was 99°F, the pulse 100, the respirations 40, and the blood pressure 220/110. The chest was very tender over the right posterior thoracic region and right shoulder, and crepitus was present. The heart was slightly enlarged, but the sounds were of fair quality. Abdominal examination was negative. It was thought that there were probably fractures of the right ribs, with puncture of the pleura and lung.

The examination was not prolonged, since the patient's condition was growing rapidly worse. Because the nearest chest surgeon was eighty miles away, it was decided to administer the best treatment possible under the circumstances.

Following a sterile preparation of the neck a vertical transverse incision was made, under local anesthesia in the suprasternal notch. The subcutaneous tissues were separated by blunt dissection. Air bubbled through the wound after the subcutaneous fascia had been divided. By means of an inverted sterile glass funnel and rubber tube attached to an electric pump, suction was secured. Considerable relief was obtained at once, and the patient's color improved. Suction was stopped after several minutes, and the patient's condition grew worse again very rapidly. Suction was reapplied, and an artificial pneumothorax apparatus, located six miles away, was sent for. With this apparatus, about 1300 cc of air was introduced into the right pleural space to collapse the lung. Suction was removed, and the patient's condition remained improved. Owing to the emphysema, no attempt was made to correct the condition of the ribs, and the patient was removed to his room at 8:00 a.m.

During the next 24 hours, suction was applied three times to relieve emphysema and discomfort. The respira-

tory rate dropped to 28, and the pulse to 96, the blood pressure rose to 145/100.

The following day the patient's condition had improved, and about half the subcutaneous emphysema had disappeared. Dyspnea was scarcely noticeable. The temperature was 100°F, the respirations 28, the pulse 88, and the blood pressure 150/88.

An x-ray film of the chest showed a complete collapse of the right lung, with displacement of the heart to the left, and three separate fractures, posteriorly, of the 3rd rib on the right side, with considerable displacement of a large posterior fragment. It also showed fractures of the 6th and 2nd ribs near the spine, with displacement.

From then on the patient showed steady improvement, the temperature, pulse and respirations dropping to normal on the 7th day. The right thoracic region was strapped with adhesive tape on that day. This might have been done before, but owing to the extensive emphysema, would have been relatively ineffective. The patient was discharged on the 9th day, free from pain and with the emphysema nearly gone. He was seen several months later, perfectly well and back at work, he did not complain of discomfort.

SUMMARY

The successful emergency treatment of a patient with traumatic emphysema of the mediastinum is described.

MEDICAL PROGRESS

CARDIOVASCULAR DISORDERS IN SCARLET FEVER*

CONRAD WESSELHOEFT, M.D.†

BOSTON

MEDICAL progress in scarlet fever has not been confined to the fields of bacteriology, immunology and chemotherapy. The cardiovascular disorders that arise in this disease have been the subject of numerous investigations, which are worthy of review.

MAJOR CLINICAL FINDINGS

The vascular disturbances of the eruptive stage of scarlet fever consist in dilatation of the periph-

ease itself is brought about by the action of the toxin on the peripheral capillaries. With this in mind, one might expect that the heart as a highly specialized organ of this vascular system would be susceptible to attack by this toxin. As a matter of fact, the heart is under certain circumstances peculiarly susceptible to the toxic products of the scarlet-fever strains of streptococci, but this susceptibility in the vast majority of cases leads to no more harm than the rash itself.

fever, therefore, resolves itself into a recital of its reported incidence. The accompanying tables give the incidence of both the bacterial and rheumatic types. Probably these include a certain number of unrecognized congenital defects. I am sure that this is true of my own earlier records. In Table 1, I have compiled the figures from 1907 to 1914 from the annual reports of the Metropolitan Asylums Board hospitals of London. Others have used the figures of isolated years, but this compilation shows the variation of incidence and its independence of the morbidity, as well as the relation of endocarditis to pericarditis. Table 2 is a compilation of published figures, including the extraordinarily low figure of Zischinsky³ and the data regarding rheumatic history in Imrie's⁵ series. My figures from the Haynes Memorial Hospital, like some of the others offered in Table 2, do not represent my consistent effort to ascertain a previous rheumatic history. Because of this review, subsequent cases are being carefully studied on this point, with the result that the findings more closely approximate those of Imrie. The total average in this substantial number of hospital cases is 0.51 per cent.

If one excludes those cases that have all the characteristics of rheumatic fever, the incidence of what may be termed a true scarlet fever endocarditis with vegetations and permanent damage becomes exceedingly rare. Zischinsky³ found only one such case among 20,000 cases of scarlet fever in the Wilhelminen Spital in Vienna. He states that he agrees with his predecessors, Pospischill and Weiss, that scarlet fever plays no significant part in the etiology of valvular disease.

The relation of scarlet fever to rheumatic fever is a subject that has brought forth many theories. Both diseases are intimately related to the streptococcus, and rarely originate in tropical climates. In both, allergic hypotheses have been advanced to explain the symptoms⁶⁻⁸. The close clinical and immunologic relation of the hemolytic streptococcus to rheumatic fever has been brought out by Mote and Jones⁹.

In scarlet fever, there is uncontroverted evidence that the erythrogenic toxin is the product of certain strains of hemolytic streptococci, although there are those who continue to believe that a virus is in some way likewise responsible. In rheumatic fever, a nonhemolytic streptococcus is incriminated in much the same way as streptococci in scarlet fever before the discovery of the Dick. Only recently evidence has been presented in support of the hypothesis that a virus is associated with the streptococcus in rheumatic fever^{10, 11}. It is generally conceded that the streptococcus, often in the form of a tonsillar infection, predisposes the

tissues to a latent rheumatic fever infection. If this hypothesis is correct, an infection with scarlet fever might likewise activate any latent rheumatic fever element, and there is ample clinical evidence that it does so.^{1, 12}

If an endocarditis develops from two to twelve months after a tonsillitis, it is promptly diagnosed as rheumatic heart disease, but if endocarditis develops in the same length of time after scarlet fever it is oftener diagnosed as a missed scarlet-fever heart lesion. Such a diagnosis is not in keeping with present day knowledge of scarlet fever and rheumatic fever. An established valvular defect coming into existence late after scarlet fever should be considered of rheumatic origin.

In connection with the rheumatic origin of endocarditis in the course of scarlet fever, it should be kept in mind that scarlet fever is a disease largely of early childhood, and therefore many potential rheumatic patients come down with scarlet fever before their first attack of rheumatic fever. Furthermore, older patients are less likely to develop valvular disease than children in the course of rheumatic fever attacks¹⁴. Consequently, these two factors reduce the chances of developing rheumatic endocarditis in the course of scarlet fever. Of course, if the valves are already damaged by a previous attack of rheumatic fever, the endocarditis cannot be said to have originated with the scarlet fever, but is merely brought into renewed activity by it.

Since Salinger and Leonard's⁷ excellent review up to 1930, the rheumatic origin of nonseptic endocarditis in scarlet fever has become quite generally accepted. According to White,¹⁴ the incidence of heart disease in rheumatic fever is 85 per cent, and in chorea 49 per cent. Granting that this estimate may be too high, the differences between the incidences in these two diseases and that reported in scarlet fever is only too obvious.

Moltschanow¹⁵ reports 17 cases of rheumatic endocarditis in the course of scarlet fever in Moscow. In 2 the endocarditis flared up in the second week, in the other 15, between the third and eighth weeks. In 14 it was simultaneous with the joint symptoms. In only 3 had there been a previous attack of rheumatic fever, yet in 7 out of 13 in which an accurate family history was available there was a definite family history of rheumatic fever. Imrie's⁵ studies are even more impressive. In 1696 cases of scarlet fever in Glasgow he had 6 patients with endocarditis, all of whom gave a rheumatic history, and in 2 a valvular lesion was found on admission to the scarlet-fever ward.

MEDICAL PROGRESS

CARDIOVASCULAR DISORDERS IN SCARLET FEVER*

CONRAD WESSELHOEFT, M.D.†

BOSTON

MEDICAL progress in scarlet fever has not been confined to the fields of bacteriology, immunology and chemotherapy. The cardiovascular disorders that arise in this disease have been the subject of numerous investigations, which are worthy of review.

MAJOR CLINICAL FINDINGS

The vascular disturbances of the eruptive stage of scarlet fever consist in dilatation of the periph-

eral capillaries of the skin—the exanthem—and those portions of the mucous membrane involved in the enanthem. Thus, the introduction to a dis-

ease itself is brought about by the action of the toxin on the peripheral capillaries. With this in mind, one might expect that the heart as a highly specialized organ of this vascular system would be susceptible to attack by this toxin. As a matter of fact, the heart is under certain circumstances peculiarly susceptible to the toxic products of the scarlet-fever strains of streptococci, but this susceptibility in the vast majority of cases leads to no more harm than the rash itself.

On the other hand, serious cardiovascular disorders may occur in the wake of scarlet fever; but the results of investigations indicate that these serious disorders are relatively infrequent as compared to those following rheumatic fever and chorea. Indeed, many—if not most—valvular defects found in the course of scarlet fever can be traced back with careful histories to a previous rheumatic or choreic infection.

The endocarditis that does originate from the hemolytic streptococcus of scarlet fever is a result of blood-stream infection and constitutes a bacterial endocarditis. Furthermore, in scarlet fever such blood-stream infection is apt to follow a local pyogenic process in the mastoid cells, associated with a lateral sinus thrombosis. place very rarely. In fact, its infrequency in cases of bacteremia suggests that a previously damaged valve may be necessary. The commoner form of endocarditis seen in scarlet fever is of rheumatic origin.

Clinical interest in endocarditis during scarlet

and then suddenly this complication ceased to appear. This supports accumulating evidence that the incidence of various complications in this disease is related to the type of streptococci²³ or to their symbiosis with other infections²⁴

Again and again the pronounced character of these murmurs suggests the possibility of endocarditis, but their benign course eliminates this diagnosis. In the absence of septicemia and unless the patient has a previous history or a family history of rheumatic fever and unless a high sedimentation rate in conjunction with polyarthritis and fever is present, I have come to take the stand that even the most marked murmurs arising in the convalescence of scarlet fever are benign in character. Under these circumstances, the chances of being wrong are exceedingly remote.

Electrocardiographic abnormalities appear to vary in their frequency quite as much as abnormal auscultatory findings. Thus Faulkner, Place and Ohler¹² found abnormal electrocardiograms in only 11 of 171 cases of scarlet fever at the Boston City Hospital. Berger and Olloz²⁵ in Switzerland found alterations in 14 out of 66 simple scarlet fever cases. On the other hand, Wickstrom²⁶ reported 86 abnormalities in 100 cases of scarlet fever at the Epidemic Hospital in Stockholm, in which those showing only a negative T wave in Lead 3 were excluded. The frequency with which abnormal electrocardiograms are reported by this author leaves one skeptical of his interpretations. The electrical alterations that Wickstrom offers as evidence of myocarditis are by no means convincing, and consequently the records would have to be checked carefully before one could accept his interpretations of what actually constitutes deviations from the normal*. The various disturbances enumerated by him showed much the same relation to the toxic stage as they did to the occurrence of late complications, no one complication showing any more of these electrical changes than another. These changes were seen with equal frequency among those toxic cases receiving antitoxin or convalescent serum and in those in which this treatment was not given. Furthermore, the alterations observed in the convalescent stage showed no consistent association with changes in the pulse and temperature. In 19 cases auscultatory signs accompanied the electrocardiographic alterations, but at other times they were entirely independent of one another. No typical alterations were apparent, but Wickstrom believed that the changes were concerned particularly with the conduction system in the left ventricle. In 40 per cent, these alterations

disappeared during convalescence, in 38 per cent during the next six months, and in 28 per cent they were still present after seven and a half months. However, with the interpretations questioned, these observations lack the necessary background to carry weight.

Shookhff and Taran²⁷ in a study of 78 normal children found slight slurring and widening of the QRS complex in Lead 1 or Lead 2 in 35 per cent, inverted T wave in Lead 3 in 25 per cent and abnormally deviated axis in 3 per cent. From ten to fourteen years of age, there was a definite decrease in the incidence of an inverted T wave in Lead 3. In 50 mild scarlet-fever cases these authors found normal P waves and a normal QRS in Lead 1 and Lead 2 and alterations in the T wave in Leads 1 and 2 in 10 per cent and an inverted T wave in Lead 3 in 40 per cent. They did not consider these changes to be evidence of myocarditis.

Van Buchem and Daniels²⁸ found a normal T wave in Lead 3 in 133, or 63 per cent, of their 211 cases of scarlet fever. It was diphasic in 13. These T-wave alterations were rarely present on admission, and in 105 they had disappeared before the end of the isolation period. These electrocardiographic findings are not peculiar to scarlet fever, nor do they constitute proof of myocarditis.

This benign character of the scarlet-fever heart is striking in comparison with the cardiac damage in rheumatic fever even when one knows that physical signs in the latter may disappear^{29, 30}. Indeed, the physical signs of the scarlet fever heart are of a will-o'-the-wisp character as compared with those of rheumatic fever.

The etiology of these benign cardiac signs in scarlet fever has been the subject of much discussion. They have been ascribed to loss of tone of the heart muscle and to dilatation. To these may be added the factor of increased blood flow. Indeed, I am inclined to believe that in some cases the abnormal sound may represent only a forceful heartbeat. On the other hand, some of the coarse murmurs at the base suggest that the signs originate in the epicardium. Probably in some cases the abnormal sounds are simply due to an overactive heart, in addition to a little transient toxic dilatation. The term, "myasthenia cordis," has been used. It has been asserted that the scarlet-fever heart is always associated with loss of body weight,³⁰ and by others that it is the result of "impoverished" blood. These last two relations have been carefully studied by von Koss and Malaguzzi-Valeri³¹ and thrown into the discard for lack of support.

First of all, Are these electrocardiographic changes peculiar to scarlet fever? They most cer-

*Wickstrom's series of 100 cases of scarlet fever was reported as showing 41 cases of disturbances in 67 intraventricular disturbances in 59 of which 75 showed lengthened QRS time and 46 deviated axis, inverted T waves in 33 and at least one of these abnormalities in 86.

tainly are not, since they are found also in many acute infections, such as tonsillitis, rheumatic fever, diphtheria, typhoid fever and pneumonia. Nor can they be said to occur with greater frequency in scarlet fever than in these other infections. They are, however, definitely related to the eruptive stage, and appear again in convalescence with or without the fever of complications, and unrelated to any particular complication. The source of these minor abnormal electrical disturbances, variable heart sounds and sudden changes in rhythm appears to be a local effect of the toxin or of some by-product of streptococcic invasion circulating in the blood stream.

Allergy has been advanced as an explanation for everything in scarlet fever, from the rash to all complications. But it is said that the purified toxin is not allergenic.³² Quite aside from the toxin, there are many other toxic products evolved by the growth of hemolytic streptococci in vivo. Furthermore, the initial damage to the reticuloendothelial cells in the eruptive stage or an antigen-antibody reaction may possibly be a factor in the causation of these benign cardiac signs. Fahr³³ is of the opinion that any attempt to work up an allergic hypothesis for the scarlet-fever heart is taking liberties with the present conception of hypersensitive tissues. However, a violent local antigen-antibody reaction affords the best explanation of the etiology of purpura hemorrhagica^{34, 35} and acute glomerulonephritis,³⁶ both of which are essentially late vascular complications of scarlet fever. Zischinsky^{37, 38} has reported 4 cases of edema of the skin due to blood-vessel damage late in the course of scarlet fever without any evidence of nephritis. This might be ascribed to endothelial-cell damage.

PATHOLOGY

Practically all autopsy material is from septic cases and therefore, of course, represents a toxic condition of the heart common to all fatal streptococcal conditions in which pus formation prevails. Scarlet-fever patients rarely die of the toxin, except in parts of Roumania. The heart in these early fatal cases may escape injury if death occurs in forty-eight hours, just as it may in early deaths from diphtheria. Here death is due to the effect of the toxin on the cerebrum, with delirium and coma accompanied by a very marked tachycardia. If death occurs later in these severe toxic cases, small hemorrhages may be found in the heart, as well as injection of the blood vessels about the bundle of His.

Fahr³³ found perivascular granulomas with large cells "not exactly identical with the giant cells found in rheumatic fever but very similar to them." Stoeber,³⁹ on the other hand, found that the blood

vessels of the myocardium were primarily injured along with the perivascular connective tissue, but to a much less extent than in diphtheria, because severe degeneration of the muscle fibers is never brought about. To him, there is no confusion between the pathology of scarlet fever and that found in diphtheria or rheumatic fever. Magladery and Billings⁴⁰ state that in scarlet fever one finds a diffuse interstitial myocarditis, whereas in diphtheria the lesion is primarily parenchymatous with secondary interstitial involvement, and that in rheumatic fever the myocarditis is almost entirely perivascular in the form of nodes. Aschoff nodes will be well developed if the patient has had a previous attack of rheumatic fever, but if the first attack occurs during the course of scarlet fever, these rheumatic elements will be immature.

Since the typical scarlet-fever heart of the second and third weeks is a characteristically benign condition, the patient who comes to autopsy must succumb from some other complication, which, in its development, would mask any underlying slight lesion if one existed. Therefore, one is not justified in offering explanations based on post-mortem findings in toxic, septic or rheumatic cases.

TREATMENT

Endocarditis and pericarditis of rheumatic origin require the usual treatment outlined under rheumatic fever, with salicylates and digitalis when indicated. However, patients with a rheumatic history who develop pain and swelling in the joints while suffering from scarlet fever often run an unfavorable course and may not respond well to salicylates.⁵ Doses in the maximum scale are frequently necessary to control pain. Digitalization, on the other hand, may be relied on when indicated in cases with old valvular lesions showing congestive failure or auricular fibrillation.

In *endocarditis and pericarditis of bacterial origin*, sulfanilamide should be given. I am speaking here on the basis of a very favorable experience with bacteremia in scarlet fever treated in this way.⁴¹ The higher scale of blood level should be used.⁴² Needless to say, if the bacteremia has proceeded to a vegetative endocarditis, the outlook is exceedingly unfavorable. In very rare cases, recovery has occurred, and immunotransfusion along with sulfanilamide offers a hope that could never be entertained before. Tapping the pericardium may be resorted to, but should be attempted only by experienced hands.

A certain amount of toxic myocarditis accompanies these cases. I have never known drugs of the digitalis group or Coramine, caffeine or camphor in oil—or I might say any drug other than sulfanilamide—to exert any appreciable beneficial effect whatever in these septic cases. Furthermore,

I am under the impression that digitalis has often made a serious condition of this kind worse rather than better.

Patients with myocarditis resulting in cardiac dilatation and failure should receive digitalis, as recommended by Hecht,⁴³ but I have not yet seen such a condition in the course of 12,000 cases of scarlet fever, except through a profound secondary streptococcal septicemia or a mixed infection with diphtheria bacilli. A case of complete auriculo-ventricular dissociation following scarlet fever is described by Bernstein⁴⁴ in which "cardiac decompensation [persisted] despite the use of all known therapeutic measures". Although I have not seen such a case, it is to be noted that Bernstein's patient was discharged from one of the best contagious hospitals, after the subsidence of the scarlet fever, with what appeared to be a normal heart. The electrocardiograph was not used in this case during the course of the disease.

Benign carditis, the so-called "scarlet fever heart", needs no further treatment than rest. This applies to the cases that show a well marked split first sound, obvious murmurs or persistent tachycardia. Abnormal electrocardiographic findings of a mild nature can be safely ignored, and the customary treatment of scarlet fever carried out. The more marked cases require rest in bed until the signs disappear. If the signs appear again when the patient is allowed out of bed, the rest should be resumed for another week, and if they again appear the patient is allowed increased activity of the most gradual form and under close observation. No medicine is necessary. It is assumed that all steps have been taken to rule out the existence of rheumatic fever.

The author expresses his indebtedness to Dr Paul D. White for the clarification of many of the uncertainties in the field of cardiology that beset one who deals with the problems of acute infections.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27221

PRESENTATION OF CASE

A fifty-three-year-old Polish housewife entered the hospital complaining of abdominal pain.

The patient felt perfectly well until the onset of general malaise six months before admission. There was, however, no specific complaint until two months before admission, when an aching pain developed in the upper abdomen, which radiated to the back and seemed to be initiated by food and relieved by fasting. Anorexia and weight loss soon appeared, so that at the time of admission her weight had dropped 40 pounds. Finally, a physician was called, who felt a mass in the patient's abdomen and sent her into the hospital.

At no time had the patient noticed chills, fever, nausea, vomiting, jaundice or change in the character of her stools. Although there were no subjective urinary symptoms, the urine had been dark for the previous two months.

The past and family histories were irrelevant.

On examination the patient was well developed and pale, and showed evidence of recent weight loss. The heart and lungs were essentially normal; the blood pressure was 175 systolic, 90 diastolic. A large, tender, freely movable, superficial mass was palpable in the right upper quadrant of the abdomen, which moved with respiration. Tenderness was present in the right costovertebral angle. A pelvic examination was negative.

The temperature was 99°F., the pulse 85, and the respirations 20.

The urine showed a + test for albumin and an orange sugar reaction. The sediment contained from 4 to 6 white cells per high-power field. The blood showed a red-cell count of 3,200,000 with a hemoglobin of 70 per cent, and a white-cell count of 7500. The nonprotein nitrogen of the blood serum was 28 mg., the sugar 272 mg., and the protein 6.9 gm. per 100 cc.; the chlorides were 96.3 milliequiv. and the carbon dioxide combining power 26.2 milliequiv. per liter. The serum van den Bergh was normal.

X-ray films of the chest and a barium enema were negative. With a Graham test there was no filling of the gall bladder, and the right kidney appeared enlarged; no stones were seen.

An intravenous pyelogram revealed the right kidney to be about twice the size of the left and slightly lobulated. The dye was excreted promptly on both sides and filled apparently normal pelvises and ureters. The substance of the right kidney appeared unusually large for the size of the pelvis; the calyces were a little long. A retrograde pyelogram on the right side was unsatisfactory because of motion. The spiderlike formation of the upper and middle calyces was again visible.

An electrocardiogram showed normal rhythm at 100, with a PR interval of 0.15 second. There was low voltage in Lead 3 and a slightly inverted T₃; Lead 4 was normal.

A cystoscopic examination one week after admission revealed nothing abnormal. Four days later an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: My function in discussing this case, of course, is to tell you what the mass in the right upper quadrant was. There are four definite possibilities that must be considered with a right upper-quadrant tumor. One of these is an enlarged gall bladder or an associated increase in the size of the liver, which we shall consider as one condition. Another is a kidney tumor. A third is a tumor of the hepatic flexure of the colon, or perhaps the ascending colon, or the beginning of the transverse colon. And a fourth is a tumor in the region of the pylorus.

To begin with the last possibility first, we have no evidence that the patient had any special gastrointestinal symptoms except for anorexia and weight loss. She felt worse after eating food, and was relieved by not eating; perhaps this indicates some interference with her digestive processes. I am a little at a loss to know why they did not do a gastrointestinal series. Apparently they did not, so that we can get no help from the x-ray findings in regard to the stomach and pyloric region. I doubt very much whether this condition was associated with the stomach, however, and I should like to pass on to the tumors of the colon. The hepatic flexure is one of the hardest parts of the colon to visualize by x-ray. We have the statement, however, that a barium enema was negative, a finding which accords with the fact that the stools were normal. Furthermore, I should not expect tumor of the hepatic flexure to be as freely movable as this was. It is possible to have a carcinoma of the cecum in which the right colon is very freely movable, that is, not fixed to the abdominal wall as it normally is. It would therefore be possible to move such a carcinoma of the cecum around quite freely. In view of the nega-

tive barium enemā and the normal stools, I do not believe that this was a tumor of the colon

The third possibility to consider is a kidney tumor, and there was evidence by x ray and intra venous pyelogram that there was an enlarged kidney on the right. It seems unlikely from the description, however, that this could possibly have been a kidney tumor, since it was described as a superficial mass and was very freely movable. The urine examination does not help us very much. The patient did have diabetes, judging from the urinary findings and the blood sugar value, but I do not believe that had anything to do with the diagnosis of tumor in the right upper quadrant.

The fourth possibility, of course, is the gall bladder. Was this mass an enlarged gall bladder? In favor of that is the location and size of the tumor, and the fact that it was described as being fairly superficial and freely movable. I am a little surprised that the patient had lost 40 pounds in weight, if this was simply an enlarged gall bladder. We have additional x ray evidence that the gall bladder was not visualized, that is, the Graham test was positive. Because of these findings I am going to make a diagnosis of hydrops of the gall bladder.

DR GEORGE W. HOLMES: So far as the x rays are concerned, the interest is centered around the gall bladder and kidney. I shall not take the time to show the chest and enema films, which were reported as negative. The Graham test, like any test in which one must make a positive diagnosis on negative findings, must always be taken with a grain of salt. If this patient had taken food during the interval, or if anything had gone wrong with the test, we should report it as a positive finding. The most striking thing is the enormous size of the right kidney. One occasionally sees a large kidney as an anatomic variation, but there is also almost invariably a small kidney on the other side. This patient's left kidney is approximately normal in size and shape, and the right kidney is not only more than twice that size but also rather round. The injected pelvis does seem to be displaced upward a little, and the upper calyx is elongated but is within normal limits. An anatomic variation might account for that, but I do not believe it would account for the size and shape of that kidney, so that I should be very much surprised if there was not disease in the right kidney. Whether that was the clinical diagnosis is another question. It does not seem likely.

DR WILLIAM B. BREED: I take it when you say hydrops that you mean a gall bladder distended with fluid.

DR LINTON: Probably clear fluid.

DR BREED: Then should you not want to give some explanation of the obstruction, such as a stone, cancer of the ampulla or something of that sort?

DR LINTON: I do not believe that hydrops of the gall bladder ever occurs without a stone impacted in the cystic duct. With a common duct stone there is always bile in the gall bladder, sometimes so-called 'white bile,' but there is seldom if ever a huge dilated gall bladder. Hydrops to the surgeon means obstruction of the cystic duct, practically always due to a stone and nothing but clear mucus within the gall bladder.

DR F. DENNETTE ADAMS: How often do you see that without superimposed acute infection?

DR LINTON: I should say quite often. There is seldom infection in this type of gall bladder disease.

DR REED HARWOOD: Do you think it would account for malaise, weight loss and anemia?

DR LINTON: The weight loss bothered me. It seemed unusual.

DR BREED: The diabetes might cause loss in weight, might it not?

DR LINTON: Yes, it might. The question is, How long was the diabetes present?

DR RICHARD H. SWEET: The X ray Department and some of the house staff were much impressed by the size of the kidney, but those who paid attention to their sense of touch would certainly have made a diagnosis of hydrops of the gall bladder. I do not believe one could have called it anything else. We operated with that diagnosis and that is what the patient had, but on freeing up the gall bladder I discovered that there was a mass of abnormal tissue in the region of the cystic duct and ampulla. It appeared to me like carcinoma. An impacted stone in the cystic duct obstructed the gall bladder. Under the circumstances it seemed to me better surgery to take it out than to drain it. We did a simple and easy cholecystectomy. The kidney on palpation was definitely large, but I could not ascertain whether there was tumor in it.

CLINICAL DIAGNOSES

Carcinoma of gall bladder
Diabetes mellitus

DR LINTON'S DIAGNOSES

Hydrops of the gall bladder, with stone impacted in the cystic duct
Diabetes mellitus

ANATOMICAL DIAGNOSES

Carcinoma of the gall bladder.
Hydrops of the gall bladder.
Stone in the cystic duct.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The gall bladder had a very thick wall, and sections of it showed adenocarcinoma of a very anaplastic character. The network of lymphatics between the gall bladder and the liver is very rich. Extension of the liver occurs so easily in cases of carcinoma of the gall bladder that chances of surgical cure are minimal. Grossly there was no obvious invasion of the liver.

DR. SWEET: There was none, but I was certain that cancer must have been left behind, in shell-ing it out from the adjacent tissues. The common duct was not involved.

DR. BENJAMIN CASTLEMAN: Had the hydrops been formed by the stone impacted in the cystic ducts?

DR. SWEET: Yes.

DR. HOLMES: You still do not know about the kidney?

DR. MALLORY: No.

DR. HOLMES: I am not convinced that it was not abnormal.

CASE 27222

PRESENTATION OF CASE

A sixty-seven-year-old man entered the hospital complaining of extreme weakness.

The patient was brought to the hospital in an ambulance, and at the time of examination displayed extreme air hunger and was unable to speak above a whisper. It appeared that three weeks before admission he had suffered a "fainting spell," and since that time had remained in bed because of an ever-increasing weakness. During these weeks before entry, he had several chills and suffered from frequency of urination, small amounts being passed at a time, with sudden stopping and starting of the stream. He had not noticed a change in the color of the urine. For the previous year he had been aware of exertional dyspnea, and had reputedly been helped by digitalis a few months before entry.

On examination the patient was well developed and lean, with a dry pale skin, dirty tongue and uremic breath. The heart was not enlarged to percussion, and the sounds were distant and of poor quality; the blood pressure was 120 systolic, 80 diastolic. The lungs were normal. Abdominal

and rectal examinations were negative. The bladder could not be palpated or percussed. The prostate was not enlarged. There was no peripheral edema.

The temperature was 100°F., the pulse 80, and the respirations 40.

The urine was acid, the highest specific gravity being 1.015; it showed a ++ test for albumin, and the sediment contained a few red cells and many white cells per high-power field. A culture yielded a moderate growth of colon bacilli. The blood showed a red-cell count of 2,850,000 with 55 per cent hemoglobin, and a white-cell count of 28,700 with 91 per cent polymorphonuclears. The non-protein nitrogen of the blood serum was 90 mg., and the protein 67 gm. per 100 cc. The chlorides were 117.6 milliequiv. and the carbon dioxide combining power 12.9 milliequiv. per liter, and the calcium 7.7 mg. and the phosphorus 4.2 mg. per 100 cc.

X-ray films of the chest and abdomen were negative.

An electrocardiogram showed sinus tachycardia (110-120), a PR interval of 0.18 second and a tendency to low voltage. ST₁ and ST₂ were sagging, and a few of the ventricular complexes had a slightly different form from usual. In Lead 3, some complexes were upright, and others inverted, but these changes were believed to be due to respiration. The T waves were low or inverted.

The patient was given intravenous fluids, digitalis and sodium citrate; closed drainage of the bladder and irrigation with potassium permanganate were instituted. On the following day, the temperature dropped to normal, but the respirations were still sighing and rapid. The urine remained about the same, although the number of white blood cells was much less. With a fluid intake of 4500 cc., the urinary output was 1500 cc., and this ratio was maintained throughout hospitalization. On the third hospital day, the temperature rose to 104°F. and the pulse to 150. Rales were present at both lung bases, and the calves were found to be tender on pressure and during forced dorsiflexion of the feet. An x-ray film of the chest showed increased density on the left side behind the heart, suggestive of consolidation. The next day the left leg was red, swollen and tender; the nonprotein nitrogen had risen to 130 mg. per 100 cc.; the chlorides were 114.3 milliequiv. and the carbon dioxide combining power 17.3 milliequiv. per liter. Peripheral edema gradually increased and involved the hands; an infected bulla developed on the left foot; terminally the nonprotein nitrogen was 143 mg. per 100 cc. Death occurred on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD J. CLARK: We are given very little information about the past history of this patient, and no inkling as to whether he had any previous renal difficulty. We first come to the story of dyspnea, which was supposedly helped by digitalis during the previous year. Yet when the patient was examined in the hospital the heart did not appear to be enlarged. The sounds were rather weak and of poor quality, as we might expect in a man of his general debility, but there were no pathognomonic signs on entry to suggest any specific primary heart difficulty. We are aware of no history of coronary or anginal pain. The electrocardiogram might suggest some degree of myocardial disease or of coronary insufficiency, but nothing specific. This makes us rather suspect that the weakness and dyspnea during the year prior to entry might have been associated with developing anemia and the beginning of nitrogenous retention, rather than being dependent on a primary cardiac difficulty. The fainting spell three weeks before entry is not sufficiently reported to give any specific clue of its nature. It may have represented a small coronary thrombosis, but there is nothing in the electrocardiogram at the time of entry that would bear that out. It seems very possible that this may have marked the beginning of an infection.

The patient entered the hospital in a markedly uremic and acidotic state, as evidenced by the physical examination and by the laboratory findings. He was very much dehydrated, and in spite of his dehydration the specific gravity of his urine apparently did not go above 1.015. He had a fairly marked degree of what I suppose was secondary anemia. There is no description of the blood to suggest any specific type of anemia. I suspect that this degree of secondary anemia probably went back farther than the three weeks of the acute illness described here, and that it was associated with a more chronic situation, which had been brewing for some time prior to entry.

With all these findings, my first thought is that the patient very probably had a chronic glomerulonephritis that had been going on for some time and was passing into the final stages of renal failure at the time he came to the hospital. He had a low blood pressure, but I suspect that before his state of marked weakness on entry it may well have been higher than the record indicates. It would be of interest to know what the eyegrounds showed, and whether there was evidence of old chronic vascular disturbance.

During the three weeks prior to entry, there was definite evidence of urinary-tract infection, with

frequency and chills. We are told that the patient had some trouble in starting and stopping his stream. This is not a very striking symptom in view of his debility. We are told that his prostate felt normal by rectum. Of course, we cannot tell what the median lobe may have been like. There was no cystoscopic examination or x-ray examination to give any lead as to the nature of the possible block in the urinary tract. The patient might have had an old stricture that flared up with the infection. At any rate, we know he had a definite colon-bacillus infection, which I am inclined to believe was primarily in his bladder. He may have had some degree of ascending urinary-tract infection, and yet he did not have any high fever at the time of entry. There is no record of pus, casts or cell clumps in his urine, findings that we might have expected with a severe degree of pyelitis or with pyelonephritis, which also has to be considered. I do not see how we can make any such positive diagnosis. Also no mention is made of renal pain. Furthermore, on the day after entry to the hospital when the patient was put on drainage and the bladder irrigated, the white cells in the urine decreased and the temperature also dropped. In spite of this, he still had marked signs of acidosis and uremia. For these reasons I am inclined to interpret this as a secondary infection in the urinary tract, which was probably not the primary cause of his difficulty. I believe that he probably had a cystitis and possibly some degree of ascending infection superimposed on previously damaged kidneys.

The question arises whether he had any other type of renal lesion. Certainly, with a story of intermittent blocking of the urinary flow, we must think of anything that produces hydronephrosis, possibly a secondarily infected hydronephrosis, which might have accounted for a fairly complete renal failure toward the end. We might also think of polycystic kidney or cancer in the course of the urinary tract. There is no history of any gross hematuria, a fact that is somewhat against these diagnoses, and no story on physical examination of any enlarged or tender kidneys, and I gather from the abdominal plates that no enlarged kidneys were made out. If the patient had been in better health, we certainly should like to have seen a pyelogram, but with the evidence at hand I do not believe that there is any definite basis on which we can make a diagnosis of any other type of kidney disturbance. The urinary output failed to keep pace with the intake, and he developed edema, evidence of water as well as nitrogenous retention, as we might well find in the terminal stages of glomerulonephritis with involvement of

the tubules as well. Under treatment there was practically no improvement of the uremia and very little change in the acidosis.

On the third hospital day, there was a sudden rise in pulse and temperature, with rales beginning at the lung bases. X-ray films at this time are said to have revealed an area of consolidation in the left chest behind the heart. Coincident with this, signs and symptoms indicative of phlebitis developed in both legs, most prominently on the left.

This brings us to the question of whether, with the sudden rise in pulse and temperature, the patient developed a pneumonic process in the lungs, or whether this represented pulmonary infarction. With the obvious evidence of phlebitis, it seems to me that infarction is considerably more likely than pneumonia. It also seems unlikely that a man so obviously moribund would have lived as long as six days after the onset of a terminal pneumonia. To be sure, there was no pain, hemoptysis or increased dyspnea; but these factors are not necessary to make the diagnosis of pulmonary embolism, which I believe the patient had.

The infected area on the left foot strongly suggested the presence of terminal septicemia, which may well have occurred with a uremic death of this type. I should say that the diagnoses were chronic glomerulonephritis, with uremia and acidosis, a fairly severe secondary anemia, cystitis, possibly ascending pyelitis, possibly median-lobe prostatic obstruction, phlebitis of the left leg, recent terminal pulmonary embolism, terminal septicemia and possibly coronary sclerosis.

DR. TRACY B. MALLORY: In any case of renal insufficiency there is always room for a wide range of clinical diagnoses. Does anyone wish to suggest any other form of renal disease as a possibility?

DR. HELEN PITTMAN: Was any search made for Bence-Jones protein?

DR. MALLORY: I do not believe so. It was not recorded.

DR. BENJAMIN CASTLEMAN: I should like to ask whether Dr. Clark thinks this man's age might be good evidence against chronic glomerulonephritis.

DR. CLARK: Yes; of course that would be a factor against it, but does not necessarily rule it out. Nephrosclerosis would be more likely at this age.

DR. BERNARD JACOBSON: I should like to ask whether Dr. Clark is not worried by the water retention. Do you think that is common in terminal uremia?

DR. CLARK: It may be present in a terminal com-

plete renal failure involving both the glomeruli and tubules.

CLINICAL DIAGNOSES

Chronic nephritis.

Uremia.

Thrombophlebitis of legs.

DR. CLARK'S DIAGNOSES

Chronic glomerular nephritis, with uremia and acidosis.

Secondary anemia.

Cystitis, possibly with ascending pyelitis.

Prostatic obstruction?

Phlebitis of leg.

Pulmonary infarction.

Terminal septicemia.

Coronary sclerosis? .

ANATOMICAL DIAGNOSES

Acute and chronic pyelonephritis.

Bacterial endocarditis (colon bacillus).

Rheumatic endocarditis, healed mitral.

Pulmonary edema.

Thrombophlebitis, bilateral popliteal, left femoral and iliac.

Cholelithiasis.

Cellulitis, left foot.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The diagnosis on the wards was the same as Dr. Clark's. At post-mortem examination the outstanding findings were in the kidneys, which were extremely enlarged, the pair of them weighing 540 gm. The capsule stripped quite readily, and it immediately became apparent that both kidneys were filled with abscesses of all sizes and ages. The pelves were not significantly dilated. The bladder showed a mild cystitis. The prostate was normal. There was therefore no particular evidence that this infection of the kidneys was ascending in character. The heart showed slight old deformity of the mitral valve and also a few fresh vegetations, bacterial in character. The post-mortem culture showed colon bacillus, a finding that we often tend to discard, but it did occur in a pure culture, and cultures from the renal abscesses also showed colon bacillus in pure culture, so that I am inclined to think this was significant and that the endocarditis was actually due to the colon bacillus. The question might be put as to whether the bacterial endocarditis was primary and the renal abscesses secondary, but I think that is rather unlikely. The extent of the renal infection

was so great and its chronicity so evident that I am quite sure it preceded the endocarditis. Both popliteal veins showed thrombophlebitis, extending on the left up the femoral and iliac veins almost to the vena cava, but no emboli had broken off and there were no pulmonary infarcts. The lungs showed a rather diffuse pulmonary edema and very questionable early pneumonia, so I think that the signs observed for a period of six days were chiefly due to edema and not to pneumonia.

DR ALFRED KRANES: What was the origin of the renal abscesses?

DR MALLORY: I do not know. We see a significant number of cases of very severe diffuse pyelonephritis for which we never find anything to

suggest the portal of entry of the infection. I think the majority of these cases run their course as cases of obscure sepsis, with not much evidence of renal insufficiency. This case was rather exceptional, since the symptoms of insufficiency predominated throughout the story. We have seen a number of cases of pyelonephritis almost as diffuse as this, with only slight terminal renal insufficiency.

DR KRANES: This must have been going on for more than three weeks.

DR MALLORY: Without any question I should think it must have run back months at least. I should assume that the patient had been having renal insufficiency since the onset of the anemia and dyspnea.

MEDICAL-COSTS INSURANCE BILL

HOUSE Bill No. 2301, sponsored by the Massachusetts Medical Society and designed to permit the formation of a corporation or corporations the function of which is to provide means of meeting the costs of medical care on a nonprofit insurance basis, was passed by both branches of the Legislature last week and was signed by Governor Saltonstall on May 22, the day of the celebration of the one hundred and sixtieth anniversary of the Society.

Permissive legislation having been granted, it now behooves the Society to take the necessary steps toward the formation of such a corporation and to devise rules and regulations, which must be submitted to the Commissioner of Insurance

for approval. Much remains to be done, but at least the initial effort has had the support of the people of the Commonwealth.

ANNUAL MEETING

THE one hundred and sixtieth annual meeting of the Massachusetts Medical Society, the oldest state medical society in the United States with a continuous existence, was held at The Copley-Plaza, Boston, May 21 and 22.

The scientific exercises were conducted through the forenoons and afternoons of both days with an attendance exceeding the capacity of the accommodations. Space for the section meetings, which were conducted during the luncheon hour on May 21, was provided in other rooms or in other hotels. The record for general registration of members, 1525, is the largest in the history of the Society. The luncheon meetings of the sections were attended as follows: medicine, 148; obstetrics, 77; pediatrics, 56; dermatology, 53; anesthesiology, 34; radiology, 13; and surgery, 85.

This meeting was reminiscent of conditions twenty-four years ago, when the medical profession was adjusting its problems to the perplexities incident to an impending world war, for doctors throughout the nation are again grappling with the exacting demands of both military and civil service for preparedness in meeting the threatening conditions in connection with another world war. Because of this situation, the afternoon of the second day was given to the presentation of important phases of war surgery.

The business of the Council was carried forward with dispatch on the morning of May 21, so that the councilors were free to attend other exercises in the afternoon. The reports of standing and special committees, the appointment of new committees and the election of officers constituted the main items of business. The officers nominated and elected are as follows: president, Frank R. Ober, of Boston; vice-president, Edward P. Bagg, of Holyoke; secretary, Michael A. Tighe, of Lowell; treasurer, Charles S. Butler, of Boston; and orator, William B. Castle, of Boston. At the adjourned session on the following day, after the

adoption of the amendments to the by-laws by the Society, George L. Schadt, of Springfield, was elected to the newly created position of president-elect; he will become president at the close of the annual meeting in 1942. All the details of this meeting will appear in the official report to be published in an early issue of the *Journal*. On the evening of May 21, the members and their guests met for the annual dinner. After a few explanatory remarks and introduction of the incoming president and the guests from the other New England states, President Walter G. Phippen presented Dr. Nathan B. Van Etten, president of the American Medical Association. His address dealt with the situation confronting organized medicine and the practitioner at the present time, with the assertion that the physicians of this country must assume leadership in strengthening the courage and purpose of the people to maintain the American standards of civilization. Dr. Van Etten stated that with the drafting of men for military training and service, forty thousand doctors will be required, so that definite responsibilities rest with those in civil life in connection with home and hospital service and medical education. He paid well-deserved tribute to the American Medical Association for its organization and support of medical education and its assistance to the Government in various activities. He deplored the lay misconception of the position that this association occupies in serving the country and upholding the traditions of the profession. His appeal for loyalty to the nation and readiness for all to serve in every possible way in promoting the successful administration of the government was well expressed. Then, Dr. Frank H. Labey, president-elect of the American Medical Association, was introduced. He emphasized the privileges of a democracy in its freedom of action, speech and the press for the individual and the minority, which is of great educational importance, but warned the audience that when the Government, after study of conditions and arguments, comes to the adoption of plans of action, all dissensions must cease and all agencies and individuals must unite in support of adopted plans; otherwise democracy will fail and disintegrate.

These moving addresses should lead to a study of the arguments, facts and opinions expressed by these two able representatives of organized medicine.

After the adjournment of this meeting, the Society convened to hear the Shattuck Lecture by Dr. Alton Ochsner, of New Orleans, under the title "Thrombosis and Thrombophlebitis." The speaker discussed the etiology, pathology and treatment of the conditions included in the title in a fashion that clarified any misunderstanding about the disabilities, the results if untreated, and the benefits following approved methods of therapy. No ordinary reference to this lecture can give an adequate appreciation of the clear and forceful presentation of the subject. Fortunately the paper will be published, and can be enjoyed by all who are interested.

The program arranged by the Ladies' Committee was most successful. A total of 175 registered, and almost all participated in the scheduled events, which included tea at the Gardner Museum, dinner at the Ritz Roof, Hotel Ritz-Carlton, and a trip to and luncheon at the South Shore.

Forty-two fellows played one or more rounds of golf in the tournament at the Commonwealth Country Club.

The annual meeting of the Society convened at eleven o'clock on the second day. The first business was the report of the Secretary *pro tempore*, showing that the Society began the year with 5542 members and that in spite of 104 deaths, 17 retirements and 49 deprivations the net gain by readmissions and restorations was 97, bringing the membership to 5639. The amendments to the by-laws of the Society that had been approved by the Council were presented and adopted, and a vote of thanks to the Committee of Arrangements was passed in recognition of the well-arranged program. The President's report on the condition of the Society showed a normal growth of this body. After a warm tribute to Dr. Alexander S. Begg, the recently deceased secretary, he complimented the Treasurer for the able administration of his office, the committees for devoted service to the best interests of the corporation and the members of district societies for their

co-operation in matters pertaining to the general welfare of the Society. He impressed on the audience that much remains to be done to carry forward the useful functions of the Society in meeting the needs of the people of the State. He urged the creation of an executive committee of the Council, as defined in the by-laws, and the selection of an executive secretary, who would be of great assistance to the officers and committees of the Society. He then presented Dr. A. Warren Stearns, who delivered the Annual Discourse.* This address stands as a notable addition to the long list of papers read at annual meetings of the Society. Dr. Stearns led the audience through the history of evolution of the human race, in comparison with individual and collective experiences with a growing forest, and finally showed where the human race stands in its responsibility to meet the needs of all classes of the population. The address was well conceived, the main theme was skillfully handled, and enough wit and humor were interspersed to keep attention focused on the facts presented.

These sketchy references to a meeting of the Massachusetts Medical Society are designed not as tributes to the standing and accomplishments of this venerable society, for none are needed, but only as hints that careful study of the papers read during the session and of the action taken by the Council is incumbent on those members who are willing to share the responsibilities of maintaining the usefulness of this organization.

TREATMENT OF BRAIN TUMORS IN CHILDREN

MODERN therapy is founded upon accurate diagnosis. Abundant examples are found in current medical teachings. In the field of infectious disease the correct use of chemotherapeutic agents should be guided by accurate knowledge concerning the nature of the infectious agent. In the field of neoplastic diseases it has been recognized for many years that the most accurate and reliable method of reaching the correct decision con-

cerning the nature of a suspected new growth is by gross and microscopic examination of an adequate sample of tissue. Lacking such a control, opinions concerning prognosis are open to grave questions, and evaluation of therapeutic procedures is practically impossible. Even more serious is the situation that occurs when the most successful means of treating a tumor are not used because of an incorrect conclusion concerning the nature of the neoplastic process. The unfortunate consequences of x-ray therapy based on inadequate diagnosis are illustrated by a paper in the present issue of the *Journal*. That the medulloblastoma is the only cerebellar tumor in infants and children has been a belief which has spread without proper support. It is possible that this impression goes back to Cushing's early work on medulloblastoma, which attracted wide attention, although he pointed out in a later paper the greater frequency of astrocytoma. In the series of brain tumors in infants and children cited by Ingraham and Campbell, the astrocytoma was actually found to be commoner than the medulloblastoma in the subtentorial region. An astrocytoma has a relatively good prognosis if removed surgically, but is not radiosensitive. A medulloblastoma is radiosensitive, and surgery, in addition to radiation, is the recommended treatment. But, even if the proportions of these two types were reversed, there is no justification for treatment of a tumor in a given patient on a purely statistical basis. Until a method is discovered of determining the nature of a new growth in a manner as accurate as that supplied by histologic examination, the generalization should be followed that no brain tumor, particularly in a child, should be treated by radiation therapy until surgical exploration has yielded sufficient material for histologic diagnosis of the tumor.

It has been only relatively recently that intracranial tumors of early life have been recognized in any considerable numbers. In the face of this distinct advance it would seem very unfortunate to lose opportunities for favorable results by instituting the wrong treatment, particularly when this treatment is based on incorrect statistical evidence.

MEDICAL EPONYM

HODGKIN'S DISEASE

Thomas Hodgkin (1798-1866), pathologist at Guy's Hospital, London, wrote a paper, "On Some Morbid Appearances of the Absorbent Glands and Spleen," which was presented at a meeting of the Medical and Chirurgical Society of London on January 10 and 24, 1832, and printed in the *Medico Chirurgical Transactions Published by the Medical and Chirurgical Society, London* (17:68-114, 1832). This treatise consists of a series of seven autopsy protocols and two case reports. Probable cases of tuberculous adenitis and leukemia were included in the series.

It may be observed that notwithstanding some differences in structure, . . . all these cases agree in the remarkable enlargement of the absorbent glands accompanying the larger arteries, namely, the glandulae concatenatae in the neck, the axillary and inguinal glands, and those accompanying the aorta in the thorax and abdomen. . . this enlargement appeared to be a primitive affection of those bodies, rather than the result of an irritation propagated to them from some ulcerated surface or other inflamed texture through the medium of their inferent vessels. . . Unless the word inflammation be allowed to have a more indefinite and loose meaning than is generally assigned to it, this affection of the glands can scarcely be attributed to that cause, since they are unattended with pain, heat, and other ordinary symptoms of inflammation, and are not necessarily accompanied by any alteration in the cellular or other surrounding structures, and do not shew any disposition to go on to the production of pus or any other acknowledged product of inflammation.

Boston

SEPARATED PLACENTA AND ECLAMPSIA
ASSOCIATED WITH CESAREAN SECTION
AND FOLLOWED BY DEATH

A twenty-four year old para III was first seen at a clinic in the thirty-sixth week of pregnancy, the blood pressure was 190 systolic, 120 diastolic and there was a large trace of albumin in the urine.

The two previous pregnancies had been uneventful, one terminated in a low forceps delivery, and

the other was normal. There was no history of any disease.

The patient was treated for toxemia in a hospital for three days, after which she left the hospital against advice. She returned to the hospital a week later because of uterine hemorrhage and very acute abdominal pain. She was not in labor.

On physical examination the heart was not enlarged, and there were no murmurs. The lungs were clear and resonant, there were no rales. The uterus was enlarged to a size consistent with her dates and was spastic. The fetal heart could not be heard. A diagnosis of premature separation of the placenta was made, and cesarean section was decided on. While being prepared for operation, the patient had a severe convulsion. A classic cesarean section was performed after a transfusion of 200 cc. of citrated blood had been given. The fetus was stillborn. Two hours after operation the patient died.

Comment. Much of the disaster in this case can be attributed to lack of prenatal care, either because of ignorance on the part of the patient or because facilities for prenatal care of patients of the very low income group were unavailable to her. She did not appear at the clinic until she was in her thirty-sixth week, at which time she had a large trace of albumin and an elevated blood pressure. Medical treatment was immediately instituted, but the patient refused to remain in the hospital. If the seriousness of the condition were sufficiently impressed on this patient before she left the hospital, the subsequent convulsion can hardly be said to be the fault of the medical profession. However, the treatment, when the diagnosis of separated placenta was made, was not that which is generally recognized as the safest.

This patient apparently had a severe external hemorrhage, which is a condition not commonly associated with separated placenta. At operation the placenta was found to be entirely separated, a large clot lying between it and the uterine sinuses. The present method of treating such eclamptic patients is to rupture the membranes, pack the cervix and vagina tightly with sterile gauze, apply a Spanish windlass, and treat the convulsions conservatively. In Boston the use of magnesium sulfate and morphine is considered the safest procedure. Some clinics are using veratrum viride in cases of this sort.

This patient was poorly handled medically after the placenta separated and after the appearance of eclampsia. Had she stayed in the hospital and had her blood pressure not come down, induction of labor would undoubtedly have been decided on, and it is likely that the final result might have been averted.

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

DEATHS

BIANCO—JOSEPH A. BIANCO, M.D., of Boston, died May 23. He was in his sixtieth year.

Dr. Bianco received his degree from Harvard Medical School in 1904. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

DALY—WILLIAM J. DALY, M.D., of Brookline, died May 17. He was in his sixty-ninth year.

Born in Boston, Dr. Daly graduated from the University of Berlin and received his degree from the Harvard Medical School in 1895. He was a former member of the Massachusetts Medical Society.

His widow, a daughter, two sons, three sisters and three brothers survive him.

FAIR—JOHN F. FAIR, M.D., of Cambridge, died May 20. He was in his seventy-third year.

Dr. Fair was physician for the Cambridge Latin School, and was a fellow of the American Medical Association and a member of the Massachusetts Medical Society.

FRAME—JOSEPH FRAME, M.D., of Rockland, died May 24. He was in his seventy-sixth year.

Born in Shubenacadie, Nova Scotia, Dr. Frame graduated from Harvard Medical School in 1894. He was assistant examiner of Plymouth County, and was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, two daughters and four sons survive him.

McCARTHY—JOHN C. McCARTHY, M.D., of Malden, died May 22. He was in his seventy-third year.

Born in Lee, Dr. McCarthy graduated from Harvard Medical School in 1891. He was a former member of the Massachusetts Medical Society.

His widow, two daughters and two sons survive him.

NAVARRO—VINCENTE A. NAVARRO, M.D., of Medfield, died May 15. He was in his forty-sixth year.

Dr. Navarro received his degree from the University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore. He was a member of the Massachusetts Medical Society and the American Medical Association.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

LAMB—ZENAS F. LAMB, M.D., of Keene, died April 28. He was in his seventy-seventh year.

Born in Athol, Massachusetts, Dr. Lamb graduated from Bellevue Hospital Medical College, New York City, in 1887. He was a member of the American Medical Association, the Cheshire County Medical Society and the New Hampshire Medical Society.

His widow, his mother and two brothers survive him.

MARKS—HOMER H. MARKS, M.D., of Berlin, was fatally injured on April 11 when he stepped into an old elevator well at the St. Louis Hospital in Berlin.

Born in Portland, Maine, in 1876, Dr. Marks graduated from Bowdoin Medical School in 1906. He was associated with the Mayo Clinic in Rochester, Minnesota, for several years.

Dr. Marks was a member of the Coos County Medical Association, the New Hampshire Medical Society and the American Medical Association.

Survivors are his widow, a son, and a daughter.

CORRESPONDENCE

HYPERTENSIVE HEART DISEASE

To the Editor: In the article, "The Development of the Concept of Hypertensive Heart Disease," by Drs. David Davis and Max J. Klainer, the statement appears, "In this country, Fahr was one of the first [1923] to appreciate the clinical significance of hypertensive heart disease."

The earliest worker in this field, if not the first, to mention, emphasize and reiterate the effects of arterial hypertension on the heart was Theodore C. Janeway (1872–1917). He mentioned it first in his book, *The Clinical Study of Blood Pressure* (1904). He reiterated it in 1906 (The diagnostic significance of persistent arterial pressure. *Am. J. M. Sc.* 131:772–778, 1906), and re-emphasized it in 1912 (A study of the causes of death in 100 patients with high blood pressure. *J. A. M. A.* 59:2106–2110, 1912). His finest report on hypertensive heart disease, one that may be pointed to without question as the classic treatise on the subject, appeared in 1913 (A clinical study of hypertensive cardiovascular disease. *Arch. Int. Med.* 12:755–798, 1913).

For reasons which are too extensive to consider here, but which are discussed by me elsewhere (Janeway on hypertension. *Bull. Hist. Med.*—in press), the excellent work by Janeway on the subject has frequently been overlooked and underestimated. I hope that this short note will aid in calling attention to his fine contributions on essential hypertension and hypertensive heart disease, which he so richly deserved.

The present war reminds us of his untimely demise. In the late autumn of 1917, after having had the general direction of the Division of Internal Medicine of the United States Army as his important assignment, Janeway made a personal investigation of the outbreaks of measles and pneumonia at certain cantonments. This, in addition to the energy required for the work at the office of the Surgeon-General in Washington and the biweekly clinics in Baltimore at Hopkins, weakened his power of resistance. Toward the end of December he became ill and after less than one week's illness of pneumonia, died at his home in Baltimore on December 27, 1917, at the age of forty-five. He was the first full-time professor of medicine at Johns Hopkins University School of Medicine under the William Welch Endowment, and served in this capacity from 1914 until his early death in 1917.

Chicago

REPORTS OF MEETINGS

GREATER BOSTON MEDICAL SOCIETY

A regular meeting of the Greater Boston Medical Society was held at the Beth Israel Hospital on March 4, with Dr. Aaron Thurman presiding. Dr. Ernst P. Boas, of Columbia University College of Physicians and Surgeons, spoke on "Factors That May Induce Cardiac Infarction." It was stated that in this condition, suggest-

nons for further clinical and laboratory studies should be the result of clinical observations.

Dr Boas discussed first the relation of chest trauma to coronary thrombosis. That thoracic blows may be sufficient to induce heart attacks has been accepted, but the mechanism is still uncertain. There may be either direct injury to the myocardium or an indirect effect on the coronary vessels through pressure from hemorrhage.

The relation of exertion to coronary infarction has been a constant source of discussion in medicolegal as well as medical circles. Dr Boas cited several cases of angina pectoris or coronary thrombosis occurring originally with or concomitant to unusual or sudden physical stress. Angina pectoris may definitely be inaugurated at the time of sudden exertion, and may persist while the patient continues to work. As to whether this may be considered a cause for disability, Dr Boas suggested that each case must be considered separately. It is believed that physical exertion may be a definite cause of coronary attacks, especially if the signs and symptoms are immediately noted. Although the subsequent onset may be suggestive when occurring within a few hours or days, one cannot be sure in such cases. In some states, the onset must accompany an unusual effort or accident.

The well known relation of emotion to coronary thrombosis and angina pectoris is a clinical observation for which there has been no adequate explanation. Sudden death may result from ventricular fibrillation following a sudden outpouring of adrenaline, or a temporary relative myocardial ischemia would make this analogous to physical effort.

Although the causative relation of allergic conditions to coronary artery disease is still controversial, there now appears to be definite evidence in favor of such a connection. That similar changes occur during anaphylactic shock in animals and in angioneurotic edema has been demonstrated. Occasional cases of anginal attacks have been observed in the process of desensitizing allergic patients, and the role of nicotine in inducing coronary changes is not unusual. Reversible changes in the electrocardiogram are present during certain asthmatic attacks.

The effect of cold has often been investigated and it has been found that cooling from any cause may induce coronary attacks, possibly by reflex coronary artery spasm. Dr Boas believes that cold weather and snow definitely increase the incidence of heart attacks. The immersion of the hands of a susceptible person in ice water may induce immediate inversion of the T wave of the electrocardiogram and may cause a coronary attack.

Certain other conditions that may contribute to coronary artery accidents are gripe and other debilitating diseases, postoperative states, hemorrhage and shock, sunstroke, electric shock, high altitudes with incident anoxia, and excessive heat and humidity. Physicians may often scoff at these external factors, yet they invariably warn against them in practice. The most plausible explanation for coronary occlusion and myocardial infarction seems to be that arteriosclerosis narrows the available vascular channels and that reflex spasm may cause a similar temporary diminution of blood flow. Under these conditions such external factors which would have no effect on a normal heart and coronary system are sufficient to cause a temporary or permanent impairment of myocardial nutrition, with subsequent signs and symptoms of coronary thrombosis or angina pectoris.

The discussion was opened by Dr Herman L. Blum, M.D., of the Beth Israel Hospital, who stated that although he had no fundamental disagreement with the

thesis of Dr Boas, he believed that everyone puts some additional burden on the heart every day or week, which might well inaugurate a coronary attack. It is only when definite signs of immediate myocardial insufficiency are manifest that one is justified in assigning any causative role to the exertion. Many of Dr Boas's clinical observations have been corroborated at the Beth Israel Hospital, where experiments have been carried out on exercise in cold rooms and in warm rooms with ice cubes in the patients' hands. It was stated that careful questioning usually elicits a definite coronary background in most cases of attacks induced by external factors except direct trauma.

Dr Samuel A. Levine, of the Peter Bent Brigham Hospital, discussed coronary artery disease under the headings of predisposing and precipitating factors. Of the former, all that is known concerns the definite role of heredity, sex and any disease with atherosclerosis—such as diabetes, myxedema, gout and thromboangiitis obliterans. The male sex predominates 3:1 in general, and 24:1 under forty years of age. Among the precipitating factors, effort easily leads in importance. Since the average person spends twenty times as much time sleeping or resting as in an active state, the incidence of heart attacks, which is twice as large while at rest as while exercising, indicates that when a correction is made effort surely plays an important role. Dr Levine believes that although immediate exertion is undoubtedly harmful, subsequent graded effort may be helpful, probably by reestablishing an adequate auxiliary circulation. The inadvertent intravenous use of adrenalin has been known to cause coronary occlusion, and it was suggested that one act accordingly rather than wait for convincing proof that in outpouring of adrenaline is harmful.

The next discussor was Dr Samuel H. Proger, of the Joseph H. Pratt Diagnostic Clinic, who emphasized that the unusual cases in which exertion in convalescent cardiac patients is not harmful should not lead one to adopt that as a standard or even advisable form of treatment. Whether angina pectoris is followed in a large percentage of cases by coronary thrombosis is apparently dependent on the astuteness of the questioning physician, as shown by a comparison of statistics from clinic patients and from private patients of reputable cardiologists. It was stated that the finding of unexplained rapid sedimentation rates in suspected cases may presage a coronary attack by weeks or months and that such findings are not common.

Dr Monroe J. Schlesinger, of the Beth Israel Hospital, reminded the group that coronary artery disease is a question of supply and demand. In regard to compensation, he pointed out that the same job day in and day out is not the same job, for it is being done by a different man. A gradually decreasing coronary supply with increasing age is a physiologic fact. Furthermore, the degree of unpreparedness probably plays a part in determining the ill-effects of unusual or sudden effort.

The discussion was closed by Dr Boas who suggested that preceding coronary artery disease is probably invariably present despite the lack of clinical manifestations. He is of the opinion that bedrest should be urged for as long as possible, and he advises four to six weeks even in so-called favorable cases. The addition of infarction may be of benefit to the patient by eliminating the infarcting artery. Enforced rest as obtained in arthritis and cerebral vascular accidents aids in diminishing coronary attacks. The danger of ingesting large meals was emphasized. Finally, Dr Boas stated that at least part of the apparent increase of coronary disease is due to better diagnosis.

BOSTON ORTHOPEDIC CLUB

At a regular meeting of the Boston Orthopedic Club on March 17, Dr. Philip D. Wilson spoke on "Recent Experiences in England." In introduction, Dr. Wilson reviewed the background for the American Hospital in Britain. He then went on to discuss the four kinds of explosives used by the attacking forces and their different effects on property and human beings. Several patients were admitted without obvious external injuries and poorly understood neuromuscular derangements. One group developed a peripheral paralysis similar to that of poliomyelitis except in its rapid clearing. Another group developed paraplegia, which also ran a short self-limited course.

Air-raid defense was briefly discussed. Experiences in the recent Spanish War proved the advantages of using bomb shelters more generally and of making more adequate shelters when possible. Although they are often inadequate, the shelters in England usually protect against any but direct hits. The subways, which originally were not supposed to be used and in which the hygienic conditions were at first atrocious, are now being rather generally employed as shelters, and the government has made surprisingly rapid and effective improvements. Whereas the workers formerly used the shelters quite often, it is now considered not only patriotic but practically as safe to continue their commuting and work with only temporary intermissions at the most. Day-time raids at best have been ineffective. Antiaircraft defense, although improving with better and more widespread radio detection, still leaves much to be desired. The new night fighters offer promise for better protection. An important item has been the use of decoy airdromes and hangars to draw enemy fire and thus waste ammunition on barren countrysides. Among the more important defense groups are the bomb demolition squads, who combine ingenuity with courage in finding and inactivating time bombs. It is interesting from a medical standpoint that auscultation is freely used to determine the presence of timing devices within a bomb and that freezing with carbon dioxide is one method of preventing the explosion of chemically constructed bombs.

Medical co-ordination is under the Ministry of Health. An emergency medical service for the development of medical units employs laymen rather than physicians. It is their duty to establish hospitals and evacuate people from danger zones. Unused hospitals and asylums have been reopened and renovated where possible, and some new hut hospitals have been constructed. In London the defense zones are pie-shaped sectors running out from a large medical school or teaching hospital in the city and extending out forty or fifty miles in gradually widening areas. The local doctors are under military orders; their salaries are small but much better than could be obtained from the poor practices that are now possible.

The American Hospital in Britain has its headquarters in an old asylum that is well heated but has comparatively poor surgical facilities. There are 1500 beds, of which 300 belong to this group. There is a large British staff, with three surgical services. This institution is the base hospital for three sectors and the evacuation center for southeastern England, especially Portsmouth and Southampton. A good supply of fresh blood, liquid plasma and dried serum is available. Those admitted to the hospital consist of two groups: any uniformed man—these make up about two thirds of the total—and civilians who are injured by the enemy, injured in civilian defense or have been under treatment in a hospital evacuated because of enemy bombs.

The type of work done by the general surgeon is largely hernias, interval appendectomies and vascular operations. The plastic surgeons, under Gillies, have been especially concerned so far with aviators, whose hands and faces are apt to be severely burned in escaping from burning planes. It has been found that tanning of these areas does more harm than the burns themselves. This is especially true of the hands, where the eschar interferes with the circulation. It also has a tendency to require too long immobilization of the hand and face muscles. The neurosurgical service has thus far been relatively inactive. The orthopedic service, on the other hand, has been busy treating fractures and other injuries, including those of many survivors of the Battle of Dunkirk.

During raids, patients are brought to first-aid centers by ambulances and are admitted by the senior surgeon for appraisal and decision about the type of treatment. The first group of patients, classified as urgent, are treated for shock with plasma and intravenous fluids. There are always one or two teams in the shock room. The second group, considered capable of immediate operation, are sent to the operating rooms after x-ray examination. Their wounds are débrided, and sulfonamides are usually employed locally. The majority of wounds are packed open, primary suture being carried out only when the patient can be followed by the original operator for the next seven to ten days, which is very unusual. The Thomas splint is being employed less than previously. There is now a definite trend toward the Orr method. There is often poor apposition of fragments, and the original fixation must be changed when the base hospital is reached. The third group consists of those with minor wounds, which are dressed; these patients are then sent to the wards.

It is characteristic of the wounds that there is a great prevalence of shock without obvious blood loss. Clinical judgment has largely supplanted determinations of blood pressure, protein levels and hematocrit readings in evaluating the status of a patient. In the surrounding countryside, emergencies are only too often seen by inexperienced men in small towns whose treatment is often ill-advised. In any questionable case of shock the patient should be established in the shock room, and the problem of infection should be only a secondary consideration.

The patients arrive at the base hospitals from a few days to several weeks after the original injury. The wounds are usually grossly infected, and it is too late even to consider surgical cleansing. Most wounds are multiple because of the multitude of secondary projectiles. The wounds are usually small on entrance and comparatively large on exit. Gas-bacillus infection is very common, but gas gangrene has been infrequent. Many wounds that have been inadequately treated must be left alone because of the danger of increasing or causing a flare-up of infection. About two thirds of all patients required revision of their original orthopedic result. They are taken to the operating room, where the wounds are opened under general anesthesia, sulfathiazole in doses of from 5 to 7 gm. being introduced into the wound. This drug is usually administered orally on the succeeding days. Because of the high incidence of comminution in the fractures, traction is usually necessary following reduction. For this purpose the Roger-Anderson or Haynes apparatus has been widely used.

Comparison was made with treatment of similar wounds in the last war. The patients do very well on the whole, with only moderate elevations of temperature for a few days. Symptoms are usually employed as the indications for changes in therapy, and the drug dosage is controlled

by blood level determinations. Pain and anxiety are largely absent, compared with patients treated by the Carrel-Dakin method, there is much less work for the medical staff, and better continuous position of the bone fragments. Under the present regimen, only 2 of 90 patients required daily dressings, and these were minor enough to be carried out by nurses. Dressings are not changed for about a month unless absolutely necessary. The odor naturally becomes very strong, but fortunately the British like the open air, and new charcoal bags are being used to absorb a large part of the smell. The first dressing is carried out under general anesthesia without any disturbance of traction.

The end results, even including cases of gas infection, compare favorably with those of the last war. It is believed that chemotherapy probably has a good local bactericidal effect. Serum has been used only on occasion, but it is thought that combined therapy is undoubtedly the best for gas-bacillus infection. If crepitation is present without gangrene, the area is incised and treated like the other wounds. There has been only one amputation, which is a marked improvement, although there may be others later. Success is attributed to the local rest afforded the wound, which favors local tissue defense, the constant pressure, which aids the circulation and especially the absence of contamination. For it is now known that hospital infection is altogether too high especially where many daily infected dressings are done. It has been shown experimentally that merely turning back the sheet over an infected wound will cause a heavy growth of the pathogenic organisms on Petri dishes placed within twenty five feet of the bed.

Unsolved problems consist of persistent osteomyelitis and delayed union or nonunion. But even if later amputations are necessary, they become elective rather than emergency measures. Nerve injuries subsequent to sinus tracts often hinder therapy, and it has been found best to do a wide resection of the infected area, with later repair of the nerve and bone grafts.

Erratum In the report of a meeting of the Harvard Medical Society, contained in the May 15 issue of the *Journal*, the phrase 'a guanidine compound' in line 36 of the second column on page 874, should read 'a pyrimidine compound (sulfadiazine)'.

NOTICES

JOHN T. BOTTOMLEY SOCIETY

The regular monthly meeting of the John T. Bottomley Society will be held in the Out Patient Department Building of the Carney Hospital on Tuesday, June 3, at 11:30 a.m. Drs. Timothy F. Lyons and Charles H. Dustin will speak on 'Intestinal Intubation'.

Physicians and medical students are cordially invited to attend.

NORFOLK SOUTH DISTRICT MEDICAL SOCIETY

The annual dinner outing of the Norfolk South District Medical Society will be held at the South Shore Country Club on Wednesday, June 11. There will be an afternoon bridge and tea for the ladies and golf for the doctors. Dinner will be served at 7 p.m. followed by an entertainment.

EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

The next examination for appointments as assistant surgeon (lieutenant, junior grade), United States Navy Medical Corps, will be held at all major Medical Department activities on August 11 to 15, inclusive. Applications for this examination must be received at the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., not later than July 15.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment, and graduates of a Class A medical school who have completed at least one year of intern training in a hospital accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association.

A circular of information listing physical and other requirements for appointment, subjects in which applicants are examined, application forms and other data pertaining to salary, allowances and so forth may be obtained from the Bureau of Medicine and Surgery on request.

An examination for appointment as acting assistant surgeon for intern training in naval hospitals accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association will be held at all major Medical Department activities on June 23 to 26, inclusive. Students in Class A medical schools who will complete their medical education this year are eligible to apply for these appointments, and if successful will receive their appointments approximately after the date of the examinations. Students in Class A medical schools who will have completed their third year of medical education this year are eligible to take this examination, and if successful will receive their appointments on or about July 1, 1942, after they have completed their medical education.

Applicants for appointment as acting assistant surgeon for intern training must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment. Acting assistant surgeons are appointed for a period of eighteen months. After the appointee has served as an intern in a naval hospital for twelve months, he is eligible for and may take the examination for appointment as assistant surgeon.

A circular of information listing physical and other requirements for appointment as acting assistant surgeon, subjects in which applicants are examined, application forms and so forth may also be obtained from the Bureau of Medicine and Surgery on request.

Assistant surgeons and acting assistant surgeons for intern training are appointed in the rank of lieutenant (junior grade), United States Navy Medical Corps. The pay and allowances for an officer of this rank total \$2699 per year if he has no dependents, and \$3158 per year if he is married or has dependents.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, JUNE 1

MONDAY, JUNE 2
12:15-4:15 p.m. Clin. copathological conference. Peter Bent Brigham Hospital amphitheater.

TUESDAY, JUNE 3
• 11:30 a.m. Intest. Intubation. Drs. Timothy F. Lyons and Charles H. Dustin. John T. Bottomley Society. Out Patient Department Building, Carney Hospital.

12:15-1:15 p.m. Clinicorontgenologic conference. Peter Bent Brigham Hospital amphitheater

WEDNESDAY, JUNE 4

*12 m. Clinicopathological conference. Children's Hospital.

THURSDAY, JUNE 5

7:15 p.m. Lecture on Cancer. Dr. Herbert L. Lombard. New England Hospital for Women and Children.

*Open to the medical profession.

BOOK REVIEWS

Chirurgie réparatrice et correctrice des téguments et des formes. By L. Dufourmentel. Preface by Professeur Pierre Sébileau. 8°, paper, 408 pp., with 451 illustrations. Paris: Masson et Cie, 1939. \$3.00.

The author has been well known for his work in reparative and plastic surgery since World War I. In this volume, he has embodied his methods of approach to various deformities of the face. He has not attempted to deal with the treatment of other parts of the body, except corrective surgery for hypertrophied breasts. War injuries, as well as civilian injuries, are covered, which is of great importance at this time.

In the first chapter, the author discusses general methods of repair, and gradually elaborates the surgical technique applied to various structures of the face. The chapter on deformities of the nose is more fully covered than those of the eyelids, ear and lips. The discussion of the repair of war injuries is interesting and has historical value, but the results obtained do not measure up to the present standards of reconstructive surgery. Reparative surgery has made much progress in the last twenty-five years and better results may therefore be expected in the repair of fractures and war injuries.

On the whole, there is much that is well discussed and instructive. The author's style is simple and direct, and the illustrations are abundant and clever. It is a valuable contribution to the literature of reparative surgery of the face, and will interest those who are in this branch of surgery, as well as those in general surgery.

The Chronicle of Crichton Royal (1833-1936). By Charles Cromhall Easterbrook, M.D., F.R.C.P. (Eng.). With a foreword, "Some Early Crichton Memories," by the late Sir James Crichton-Browne, M.D., LL.D., F.R.S. 4°, cloth, 663 pp., with 103 illustrations and 1 map. Dumfries, Scotland: Courier Press, 1940. 25 sh. net.

This large book is a detailed history of one of the famous mental hospitals in Scotland, covering a period of over one hundred years. The first report of the hospital was issued in 1840. The founder was James Crichton, who studied at the University of Edinburgh, and while still a youth went to India, in the service of the East India Company. He became physician to the Viceroy, but also found time to make a fortune by trading in India and in China, and returned to Scotland in 1808, when only forty-three years of age, a rich man. It was with this fortune that he endowed the Crichton Royal Institution, a hospital staffed with the best of Scottish physicians for over one hundred years. The book is fully illustrated with photographs and portraits, and there is an extensive index. It forms a record of enduring work.

A Handbook of Hearing Aids. By A. F. Niemoeller, A.B., M.A., B.S. Foreword by Harold Hays, M.D. 8°, cloth, 156 pp. New York: Harvest House, 1940. \$3.00.

This is a description in nontechnical language of the different types of hearing aids and the methods of using them to best advantage. At the end of the book, there is a complete list of hearing aids and the companies that manufacture them. This book should be in the office of all otologists who are interested in treating the deaf and aiding them by means of hearing apparatus.

NUMBER 23

CESAREAN SECTION IN MASSACHUSETTS IN 1939*

ROBERT L. DeNORMANDIE, M.D.

BOSTON

THE following report on cesarean sections performed in Massachusetts in 1939 is the third in the five-year study.[†] Three additional questions were included in the questionnaire this year—the name of the consultant, the name of the operator and the birth weight of the baby.

The questionnaires were sent to one hundred and seventy-two licensed maternity hospitals, and replies were received from all but two. One hospital had been closed, and the records were not available. How many cesarean sections were done in this hospital is not known. It was found, however, that in 1 cesarean section done there the patient died after transfer to another hospital. The other that did not reply was a small hospital that had changed ownership. Its records were not available. In forty-two small hospitals, no cesarean sections were performed.

* * *

In Massachusetts in 1939 there were 62,575 live births and 1765 stillbirths, a total of 64,340. Of these, 52,697 were reported to us as having occurred in hospitals. There were 1984 cesarean sections performed and 12 hysterectomies, a total of 1996 abdominal deliveries, or an incidence of 1 in 32.2, compared with 1 in 30.3 in 1937 and 1 in 28.7 in 1938.

Table 1 gives a summary of the abdominal deliveries. The only significant change in this table is the marked increase in the number of sections of the extraperitoneal type. There were 20 in 1937 and 14 in 1938, compared with 34 in 1939. The reason for this increase is the new operative technic developed by Dr. Waters. There were 31 cases of the Waters type, 1 of peritoneal exclusion and only 2 of the Latzko type.

A short analysis of these 34 cases is interesting. Of the 31 patients on whom the Waters operation

was performed, 17 made uneventful recoveries. Of these, however, 4 were not in labor, nor were the membranes ruptured; the operators obviously wished to try out the new technic. Of the 13 remaining cases of uneventful recovery, 7 patients

had unruptured membranes, and 4 of these were in labor only eight to fourteen hours. The remaining 3 had labors of twenty-five, forty-eight and seventy-two hours. Of the 6 patients with ruptured membranes, 4 were in labor twenty-eight to thirty-six hours, with membranes ruptured from ten to thirty-two hours. One was in labor thirteen hours, with membranes ruptured twelve hours, and at operation a large hydrocephalic baby weighing 11 pounds, 5 ounces was delivered. In the last case in this group, forceps delivery was attempted twice but failed. This case I shall discuss later.

In the remaining 17 cases with the extraperitoneal type of operation, 2 patients died, and the others were reported as having had febrile convalescences. This group includes the 2 Latzko operations, the peritoneal exclusion and 12 of the Waters type. The answers to the questionnaires do not give the complete picture of these cases, and it is not fair to comment too harshly without

*Read before the Fall River Medical Society, January 25, 1941, and before the Boston Obstetrical Society, February 18, 1941.

[†]The other two were published in the December 1, 1938, and July 11, 1940 issues of the *New England Journal of Medicine*.

further study. I record the summary of the analysis. The 2 patients that died, both following Waters operations, I shall refer to later under maternal deaths.

One patient on whom a Latzko operation was performed was in labor for thirty-six hours, with membranes ruptured for forty-eight hours. She is reported to have had a temperature on entrance to the hospital. She had a stormy convalescence, with a fever during her entire stay in the hospital, and was finally discharged from the hospital with a draining wound. The other patient on whom a Latzko operation was done was in labor, with ruptured membranes for eighteen hours. She had distention and fever for some days, but was discharged well. Both babies were discharged well. At birth they weighed respectively 7 pounds, 2 ounces, and 6 pounds, 14 ounces.

In the peritoneal exclusion case, the patient was in labor sixteen hours, with ruptured membranes ten hours. The baby was presenting by the breech and was delivered alive. The only note made on this case was that the convalescence was febrile.

The 12 cases of the Waters type of section that had febrile puerperiums remain to be analyzed. Two patients were not in labor, and the membranes were not ruptured. Of the remaining 10, 4 were in labor from twelve to twenty-three hours, and 6 from twenty-four to forty-eight hours. Of these 10 cases, in 1 the membranes were not ruptured, in 1 they were ruptured less than eleven hours, in 5 from twelve to twenty-three hours, in 2 from twenty-four to forty-seven hours, and in 1 forty-eight hours. The type of labor is not recorded in all, but in several it was noted to be only fair or poor, and in a few it was reported to have been hard.

The following complications were reported as occurring in these 12 patients. Two developed bronchopneumonia, and 1 a so-called "upper respiratory infection." Three developed pyelitis. One was reported as having septicemia, pneumonia, pulmonary embolus and empyema, and was transfused twice. Another was reported as septic, developing a pelvic phlebitis, pyelitis and embolus, and was twice transfused. Another, reported as having a febrile puerperium with endometritis, had an embolus. One is reported as having had a stormy convalescence, which was never serious. The 2 final cases were simply reported as septic. In this group, all the babies lived.

The number of Porro operations performed—26—is approximately the same as that in the two previous reports. Two of the 26 patients died. There is no need to analyze all the indications for these Porro operations, since they will be taken

up later under the various indications for operation. There are, however, several that should be commented on here, because they might otherwise be overlooked. In 4 cases no recorded indication is given in the questionnaires. In 1 of these cases a Porro operation was done after a twelve-hour test of labor with a breech presenting. The baby weighed 6 pounds, 8 ounces. Two other cases were repeat elective sections. The fourth operation was done on a forty-four-year-old primipara following a twelve-hour labor, and a contraction ring was found. The baby in this case was stillborn. A thin scar of a previous section was the recorded indication for 1. In 1 case a branch of the uterine artery was torn at the

cesarean section, and a Porro operation was done at once. In another case, an elective repeat section, the uterus continued to bleed, and a Porro was thought to be indicated. The baby in this case weighed but 5 pounds.

The final case in this group on which I wish to comment is that of a patient with membranes ruptured fourteen hours, in labor twelve hours. It is recorded that free pus was found in the uterus, yet the patient made an afebrile convalescence. The baby weighed 11 pounds, 8 ounces, and died on the eighth day. At autopsy both kidneys showed free pus.

Table 2 shows the indications for the 12 hysterot-

omies. These are clear, and no comment is necessary.

Table 3 records the types of anesthesia. The use of spinal anesthesia has increased slightly, and the use of cyclopropane has dropped. The others remain in relatively the same proportion. Un-

der the heading "Other" are grouped various combinations that were used and some of the newer anesthetics. Two deaths apparently must be assigned to anesthesia, and they will be reported under the maternal deaths.

Table 4 shows the reported indications for operation in cases in which the baby died. Although

the actual number of babies lost is lower, the percentage is slightly higher than that in 1938.

It is difficult to tell from the questionnaires in how many of these sections the first two indications in Table 4 were for the best interests of the patients. Undoubtedly many were questionable, for some were done at five or six months' gestation, and in many of the previas the babies' weight was reported to be 4 pounds or less. One such patient, on whom a Porro was done, is reported as having moderate bleeding at six months.

Under "Toxemia and nephritis," 12 babies were lost. There is always a serious risk to the babies in these cases, and the loss of 12 is not surprising. It is only by careful prenatal care that the number and severity of the toxemias can be reduced, and so long as such care is not given deaths from this cause will continue.

Thirty-two babies were lost following cesarean section done because of a previous section. Of the 10 classified under "Emergency," 3 were lost because of ruptured uterus, 3 because of premature labor, — the babies weighing less than 5 pounds, — 2 because of separated placentas, — 1 of these babies being macerated, — 1 because of erythroblastosis

and 1 because of alleged congenital heart disease, although no autopsy was performed.

In the elective repeat sections, 22 babies were lost. The cause of 7 of these deaths was atelectasis or prematurity; 4 infants had malformations incompatible with life, 2 died from erythroblastosis; 2 died from toxemia; 2 were stillborn, 1 of these being macerated; 1 each died from hemorrhagic disease of the newborn, cerebral hemorrhage and congenital heart disease; and 2 died from complications arising after birth, 1 from abscess of the lung and 1 from bronchopneumonia.

It is obvious that some of these deaths were unavoidable, but unless all the 32 original cesarean sections were necessary, through the repeat sections the patients were subjected to an operative procedure that failed to give a living baby.

It is difficult to explain why the babies were lost in many of the elective sections. It seems hardly reasonable to perform a section on a known malformed fetus, and it is a doubtful procedure on a patient presenting hydramnios.

As in the elective sections, some of the emergency deaths were unavoidable. But the loss of so many babies shows conclusively that the choice of a cesarean section in some cases was, to say the least, questionable. It must be recorded that in 4 of the emergency sections the fetus was macerated. Reasonably good judgment was lacking.

Table 5 shows the indications given for operation. It is arranged approximately as that in the other reports.

There is no need to comment on each indication. Contracted pelvis and disproportion total 336. Of these, 179 were classified as contracted pelvis. One hundred and thirty-seven of the 179 patients had no labor. One baby weighed under 5 pounds, 14 under 6 pounds, 51 under 7 pounds and 61 under 8 pounds—a total of 127 babies of average size. One woman said to have had a large baby was operated on and delivered of twins. There were 39 babies weighing over 8 pounds, and 12 cases in which the birth weight was not recorded. One hundred and fifty-seven cases are classified under "Disproportion." Seventy-four of these had no labor, and a section was done presumably because the operators regarded the babies as too large for a normal delivery from below. Analysis of the weights of the babies shows 2 under 5 pounds, 2 under 6, 21 under 7 and 57 under 8 pounds. Seventy babies weighed 8 pounds or over, and in 5 cases the birth weight was unrecorded.

Under the indication "Contracted pelvis," 82 cesarean sections were done without consultation, but under "Disproportion," there were only 40.

Farther down in the list of indications, 164 cases are classified under "Test of labor." In these, 1 baby weighed under 4 pounds, 1 under 5, 4 under 6, 23 under 7 and 47 under 8 pounds. There were 74 weighing 8 pounds or over, and in 14 cases the weight was not reported.

If the number of babies weighing under 7 pounds in these 3 indications are added together, the total is 120, or 24 per cent of the 500 cesarean sections

labor under twelve hours, 2 from twelve to twenty-three hours, 13 from twenty-four to forty-seven hours, 3 from forty-eight to seventy-two hours, and in 2 the length of labor was not reported. In this group, 4 babies were lost and there was 1 hydrocephalic case. Six of these women developed severe puerperal sepsis, but all, fortunately, recovered. Seven of the babies weighed under 7 pounds, and 1 of these was under 6. Several of the babies

performed. But the total number of babies under 8 pounds is 285, or 57 per cent of the number of sections done for these three indications. There can be but one conclusion from these figures: that a large number of the sections are totally unjustified.

I have already spoken about the questionable procedure of performing sections on some of the patients with placenta previas and separated placentas.

There has been a marked drop this year in the number of sections for toxemia, but the number for eclampsia remains about the same. In the 11 cases of eclampsia, 2 mothers and 3 babies died.

Under the indication "Dystocia," there were 9 cases. In 1, labor was mild, and the length was not reported. The other 8 had labors of from thirty-four to seventy-two hours. Two cesarean sections were by the Waters technic, and the others were of the low type. All the babies were discharged well. Five of these patients had febrile puerperiums and for a time gave considerable worry to the operators.

There are 23 cases under "Labor without progress." Two patients were reported as having

that died were not weighed. It is well to note here that all babies should be weighed, whether they are born alive or dead, for comparison in future deliveries.

Twenty-four cases are classified under "Cervical dystocia." In 1 the operation was done before labor began, because of a badly scarred and lacerated cervix. A second was done after eight hours of labor for "cervical atresia." Two of the patients in this group were in labor for two days, 2 for three days and 1 for four days, but the significant remark was made in this questionnaire that the patient had "several bouts of false labor during this time." All the other patients were in labor from eighteen to twenty-four hours, except in 4 cases in which the length of labor was not reported. In 15 cases the membranes were not ruptured. Six of these patients had a febrile puerperium. All the babies were born alive. Six weighed under 7 pounds, and 1 weighed only 3 pounds, 13 ounces. One mother died, and this case will be discussed later.

No comments are necessary on the 36 cases classified under "Previous surgical operations," except to note that following an amputation of

the cervix the section should, if possible, be an elective and not an emergency one

Under "Associated medical conditions" there are 51 cases. It is an interesting fact that because of the control of diabetes by the use of insulin, the number of diabetic patients who become pregnant is increasing. All the mothers and all but 2 babies in this group lived.

No babies died under the indications "Fetal distress" and "Prolapsed cord." In 2 of the latter cases the prolapsed cord was in the first of twins. In 1 of these cases the mother had an extremely stormy convalescence, was septic, developed a phlebitis, but eventually recovered.

In 1 case of "Fetal distress," it was noted that the mother had no labor but that the fetal heart was slow. A section was done, and a baby weighing 5 pounds, 8 ounces was delivered. The heart continued slow, and a diagnosis of congenital heart block is recorded.

Again I regret having to report cesarean sections done following operative attempts at delivery from below. At best it is a dangerous procedure, and should not be attempted unless the previous operative attempts have been made with most meticulous care. The seriousness of this procedure is demonstrated by the fact that 4 mothers and 3 babies died in cases in which operative attempts had failed. The maternal deaths I shall report later in this paper. There is 1 case, however, on which I wish to comment, not as an illustration of good obstetrics but of good luck. After two days of slow, irregular labor, the patient became fully dilated. The head remained high. A forceps was applied by the house officer without success. The visiting surgeon was sent for and the note on the questionnaire says, "With considerable amount of pull, no give for him. Therefore a cesarean was decided on." It is recorded that a Waters type of section was done, and the patient made an uneventful convalescence, the baby weighing 9 pounds, 7 ounces.

Regarding the indication "By request or for sterilization," I can only repeat what I have said so many times before: that to me it is utterly unjustifiable to do a cesarean section simply at the request of the patient or only to sterilize. In 1 section done at the patient's request, the baby was lost. The surgeon who operated must have found it difficult to justify such an operation with the loss of the baby.

Under "Ruptured uterus," 2 spontaneous ruptures were reported and 6 cases in which previous sections had been done. All the mothers lived and 3 babies were born alive. One of these patients had had a longitudinal low flap section in

the first pregnancy, followed by two normal deliveries. In this, the fourth pregnancy, rupture occurred after twenty-four hours of labor, the baby weighing only 5 pounds.

Another interesting case in this group is that of a patient admitted to a hospital in shock. The operator writes:

The ovum was found to be completely in the abdominal cavity and the uterus well shut down with a rupture extending from the left cornu to the region of the cervix on the right side. There was a good deal of amniotic fluid in the sac, which was opened to extract a dead baby. The tear in the uterus was repaired and a drain placed to the pelvis. The patient made an uneventful recovery. She later returned for sterilization.

This case is classified as a spontaneous rupture. The patient had been in labor for two or three days, and had been etherized, but it was reported that she had not been operated on.

Under the indication "Postmature," there is only 1 case on which I wish to comment. The questionnaire states, "Head not in the pelvis, overdue two weeks." A section was done without a consultation, and a baby weighing 5 pounds, 8 ounces, was delivered.

The indication for 4 sections is given as "Malformation of the fetus." Three were hydrocephalic, and 1 was anencephalic. This does not mean that these were the only malformed babies in this series, others occurred, but the malformation was not the primary cause for the section, as in these 4 cases.

Two of these cases, it is recorded, had x-ray examinations. In 1 case the baby weighed 5 pounds, 8 ounces, and as it was being delivered through the incision the head collapsed. The notes on the second case say that "the patient had two premature births at five and six months, and both children died. In view of the x-ray findings and a very large child, it was thought best to do a cesarean section." The weight of this anencephalic monster is not given. In 1 case the baby weighed 11 pounds, 5 ounces, but it is not recorded that an x-ray film was taken. The final case also has no record of an x-ray examination. The baby weighed 7 pounds, 8 ounces, and the patient was operated on after, it is said, three days of labor. She had a pulmonary embolus, which eventually cleared up.

The 1 case of "Error in diagnosis" was that of a general surgeon operating for a large ovarian cyst.

The "Surgical emergency" was the case of a woman brought to the hospital *in extremis*. The abdomen was opened, and pus poured out. The patient had had no previous medical care. The baby was stillborn, and the mother died on the table.

Thirty-two sections were for indications class

sified as "Bizarre." I shall not attempt to enumerate each of these indications, but I do wish to mention a few: "A highly resistant luetic"; "distinct endocrine type"; "severe pain in the right lower quadrant"; "undilatable soft parts" (this patient was not in labor, a cesarean was done, and the baby weighed 5 pounds, 14 ounces); "interlocking twins"; "multiparity." Three sections were done for so-called "dystocia," yet 2 patients had no labor and 1 had labor for only four hours, and the babies weighed respectively 6 pounds, 2 ounces, 5 pounds, 1 ounce, and 7 pounds, 2 ounces. There were 2 cases of cervical dystocia, but the patients had no labor. One baby weighed 6 pounds, 15 ounces, and the other eight pounds. These 2 cesarean sections were done by the same surgeon. It is obvious that he wanted to do a section on the patients. There is no recorded adequate indication. Three patients were said to have a floating head, and were not in labor. One indication was "primary inertia with torsion of the uterus." There was no labor. In

a final case the patient was said to have had a previous dystocia in her first labor, but did not go into labor this time. A 6-pound baby was delivered.

It is reported that 68 patients were sterilized at the time of the section.

Table 6 presents a summary of the 54 cases with maternal death. It needs no comment.

In Figures 1 and 2 the data on the maternal deaths are presented in the same manner as in 1938. Figure 1 analyzes the 9 elective sections, and Figure 2 the 45 emergency operations in which death occurred. Some of these cases have already been remarked on. Others need no analysis.

For 1939 there was an encouraging drop in the number of deaths following elective section, only 9 cases being so classified.

Of the 4 deaths giving sepsis as the cause of death, the indication was "contracted pelvis" or "disproportion" in 3 and "repeat section" in 1. This last patient was prepared for operation one

morning, but the membranes ruptured during the night and a section was done within an hour. One patient had a hard operative delivery with the first baby and a large baby in the present pregnancy. She was sterilized following the cesarean section, and the appendix was removed. The operator, a general surgeon, did not ask for a consultation. In this case the sepsis may have originated from the appendectomy. It is a possible cause,

FIGURE 1. Maternal Deaths in 9 Elective Cesarean Sections

and therefore this operation at the time of a cesarean section is always contraindicated.

The third patient was a dwarf with a contracted pelvis. On entrance to the hospital it is reported that she had a temperature of 101°F., with a negative physical examination. Distention occurred in twenty-four hours. The temperature and pulse continued to rise, and the patient died on the morning of the fifth day. The death certificate gave "paralytic ileus" as the cause.

In the final case of sepsis, a staphylococcal bacteremia, section was performed because of a "pelvic outlet smaller than the average." The baby weighed 6 pounds, 13 ounces.

The 2 deaths from embolus were in repeat sections, one occurring on the sixth day and the other as the patient was being helped up the steps to her home on the eleventh day.

The cardiac patient was decompensated, was operated on under local anesthesia, grew steadily worse, and died on the sixth day.

The death assigned to anesthesia occurred in a repeat section. The patient took the anesthetic poorly and had to be resuscitated in the middle of the operation. Twelve hours after operation she developed considerable distention, with a temperature of 102°F. Distention increased, the tem-

perature ranging about 103°F, she died on the sixth day. The death certificate gave bronchopneumonia as the cause of death.

The final death following elective cesarean section occurred in a repeat section three hours after operation. The cause of death on the certificate was "surgical shock, embolus." When the operator attempted to remove the placenta it was found to be an accreta. The patient bled profusely, and a Porro operation was done immediately. Salt solution was given subpectorally at once. While preparations were being completed for

and in spite of intravenous fluids, sulfanilamide and a transfusion, died on the seventh day.

The other 8 cases, not so designated by their physicians, I have placed under sepsis because of the history that was obtained in the maternal mortality study, and they may need explanation. In 4 cases the cause given on the certificate was "paralytic ileus," with or without toxic or acute myocarditis, and in 1 case the cause given was "acute dilatation of the stomach." There can be no question that these 5 deaths should be attributed to sepsis. In 1 case the certificate gave "uremia" as the cause of death. The patient did have suppression of the urine, but she also was septic. Another case gave "toxemia and hemorrhage following a separated placenta" as the cause of death, but from the interview with the physician and from the hospital record the death was definitely thought by the investigator to have been caused by sepsis. In the final case the cause of death on the certificate was "right lobar pneumonia." The evidence in this case is not conclusive, but the facts as brought out by the study are these: After seventeen hours of labor, the cervix being dilated to admit three fingers, a version was attempted on a hydrocephalic baby. It was unsuccessful. One hour later the patient was again etherized, and again the version failed. At this time a ruptured uterus was suspected. The temperature was found to be 104°F, the pulse 140. The patient was then etherized a third time, and a Porro was done because of this ruptured uterus. Death occurred fifty-two hours after operation. There was a suggestion that the patient had an upper respiratory infection on entrance to the hospital, but no temperature was recorded on the questionnaire. She may have died of pneumonia, but I have assigned the death to sepsis. No matter to what cause the death is attributed, it was the result of bad obstetrics.

Of the 7 deaths from shock, 5 followed separated placenta. In 1 of these cases there was a delay of four hours in getting the patient to the hospital, a distance of ten miles, because of a very heavy snowstorm at the time. Two cases of shock followed failure of previous operative attempts.

In the 3 deaths assigned to hemorrhage, 2 followed operations because of separated placenta, and in 1 a cesarean section was done after operative attempts at delivery from below had failed. In 1 of the first 2 cases the patient oozed from a pinprick of the ear, and from a vein where a transfusion was done. Two of these deaths from post partum hemorrhage occurred in the same hospital two to four hours after operation and raise

FIGURE 2 Maternal Deaths in 45 Emergency Cesarean Sections

transfusion, the patient died. In this case there was a delay of at least two hours in transfusing. Had this patient been transfused promptly, her life might have been saved.

Forty-five patients died following emergency sections. In these cases, 22 deaths were assigned to sepsis. Fourteen were so designated by their physicians on the death certificate.

One of these cases I report in detail. The patient was a thirty-year-old primipara in labor some forty-five hours, with membranes ruptured an unknown number of hours. Dilatation was very slow. Two vaginal examinations were made. A section was finally decided on. The temperature was reported as 102.6°F. Before the section, of the classic type, was done by a general surgeon, a low pressure 5 gallon douche was given. After the operation, the patient showed signs of sepsis,

the question whether the nursing care in these cases was adequate. Should they be regarded as preventable deaths?

Two of the patients whose deaths were assigned to embolus ran septic temperatures (1 following a Waters type of cesarean) for over a week, and from the questionnaires one wonders whether they were not allowed up too early. It is to be noted that in 1 death assigned to embolus the indication was "the wish of the patient."

The deaths assigned to pneumonia and eclampsia need no comment.

The case attributed to pulmonary edema occurred in a primipara with toxemia. She was in labor some twenty hours, and by the hospital record fully dilated for five hours when a cesarean section (Waters type) was done. At the operation the patient bled more than an average amount. Following operation she passed bloody urine, and twelve hours postoperative the temperature was 102°F., the pulse 140, and the blood pressure 186 systolic, 80 diastolic. Twelve hours later she suddenly developed pulmonary edema and died.

The next death was that of a patient operated on for placenta previa. The note from the obstetrician who investigated this death states that the post-mortem examination, which was performed by a capable pathologist in the presence of several clinical observers, completely failed to reveal the cause of death. The proper diagnosis remains "unknown."

The cardiac death occurred in a woman with long-standing cardiac disease in her tenth pregnancy. She was admitted to the hospital in the seventh month, with partial decompensation. While in the hospital under treatment she began to bleed from a placenta previa. A section under nitrous oxide, oxygen and ether anesthesia was done at once. The baby, weighing nearly 5 pounds, lived, but the mother died on the second day.

The death assigned to anesthesia occurred in a patient who weighed 240 pounds. She had been in labor twenty-four hours. The anesthetist tried for an hour and ten minutes to anesthetize her with nitrous oxide and oxygen. Failing in this, she was given Epival intravenously, and a low section was done at once. The temperature immediately rose to 102°F., with respirations of 40 and rales throughout the chest. She became very dyspneic and cyanotic, and died on the second day.

The last patient in this group had had eclampsia with her first pregnancy and a separated placenta with the third, in both of which cesarean sections had been performed. She had a separated placenta with this, the fourth, pregnancy. The systolic blood

pressure before operation was 220. The patient passed no urine for four days, and died on the seventh day.

* * *

This report shows an encouraging drop in the number of cesarean sections performed in 1939, but it also demonstrates conclusively that too many sections are still being done in Massachusetts.

Cesarean sections figured in 21 per cent of the total number of maternal deaths, demonstrating that this procedure is a major cause of keeping up maternal mortality in the State.

One thousand and ninety consultations are reported, but the consultation in many cases was the mere formality of having a surgeon see the case before he operated.

In some communities a trained obstetrician is not available to lend aid in difficult problems, and the physicians turn to surgeons for help in what appears to them to be serious situations. Few of these surgeons have had any training in obstetrics. They know how to do nothing in the obstetric field, yet do not hesitate to subject a woman to what in many cases is an unnecessary operation.

There are relatively few patients who cannot have the advantage of a really valuable consultation if their physicians give them adequate prenatal care. In most cases, cesarean section should not be an emergency operation, and therefore if a physician wishes and has the best interests of his patients at heart he can always obtain competent help, and need not rely in an emergency on an untrained surgeon who is willing to cut without any desire to think.

One hundred and seventy-three babies were lost. This total is too large and must be lowered if our results are to be regarded as satisfactory. Careful evaluation of the proper method of delivery was not present in many cases. To subject a woman to a section when the baby has a known malformation incompatible with life is not good obstetrics and is not demanded by any religious dogma. Such indications must be eliminated.

Sepsis, as we all know, has been the major cause of deaths from cesarean section, and 1939 was no different from any other year. That 50 per cent of the deaths should be from this cause is a serious criticism of the operators, and as I have said before, these operators must revise both their technique and their judgment in choice of operation. In neither of these points can they be regarded as suitable operators unless marked improvement is shown.

On many previous occasions I have called attention to the fact that the deaths following cesarean section are scattered; no one operator has

several. For 1939, twenty six hospitals reported 1 death each, nine 2, two 3, and one 4. In the last hospital 31 cesarean sections were performed, and in 2, death followed post partum hemorrhage. Such a result is a serious criticism of the hospital, and the cause should be studied and speedily rectified.

The variation in the incidence of cesarean section in large clinics is interesting. How much criticism one can justifiably make is uncertain, but the facts are undeniable. In the two largest clinics in the State the respective incidences were 1 in 36 and 1 in 33, whereas in two other hospitals in the same city the respective incidences were 1 in 11 and 1 in 17. The four largest clinics in another city show respective incidences of 1 in 48, 1 in 40, 1 in 28 and 1 in 19. The complete story is not told by the questionnaires, but one fact is obvious: the major difference in the incidence occurs when private patients are included in the total figures.

The committee appreciates the co-operation shown by practically all the hospitals in filling out the questionnaires. There was, however, a great variation in the care shown in the answers. The

large majority of hospitals filled out the questionnaires fully and carefully, but in a few, usually the smaller ones, the answers were not always satisfactory. In one proprietary hospital in Boston no indication was given for any cesarean section done. In another hospital, no records were filled out for one physician's private cases.

The replies to the questions concerning consultant and operator were so incomplete that no attempt was made to draw definite conclusions. It is clear, however, that in many cases a general surgeon operated, and that no adequate consultation was held.

In many of the hospitals the rule of the American College of Surgeons that all major obstetric operations call for a consultation is being enforced, but not in all. In some hospitals the physicians are graded in relation to what they are allowed to do, and this obviously is a step in the right direction. Until this is done in all hospitals, whether it be in surgery or obstetrics, poor results will continue.

TUBERCULOSIS AND MOBILIZATION*

FREDERICK T. LORD, MD†

BOSTON

VOLUNTARY tuberculosis associations throughout the United States have a responsibility in connection with mobilization to urge the exclusion of tuberculous men from the Army, and to help in every way possible in the follow-up of those rejected because of the disease. Adamson¹ reports that the Defense Department of the Dominion of Canada has ordered a chest x-ray examination of every recruit. Standard films and technic have been used. The percentage of rejections for tuberculosis have amounted to 106

Tuberculosis and Mobilization, 1917-1918

In 1917 and 1918, under the selective service regulations, reliance was placed on physical signs for the exclusion of pulmonary tuberculosis. No mention was made of the use of x-ray films in this connection, but registrants were at times thus examined by medical advisory boards. I was at that time a member of an advisory board and placed much more confidence in physical signs for the discovery of pulmonary tuberculosis than

I do now, and called for an x-ray examination only in selected cases.

The selection of registrants for service in 1917-1918 was made under pressure in the face of an emergency. Many men with tuberculosis entered the service, and the magnitude of the tuberculosis problem in disabled veterans may be judged by the cost, which for hospital care, insurance benefit in excess of paid in premiums, vocational training and compensation, is estimated by Spillman² to have amounted already to approximately \$950,000,000.

The tuberculosis problem was much more serious in the United States then than it is today. In Massachusetts, for example, the death rate from the pulmonary form of the disease in 1917 was 121, and in 1940 it had fallen to 34 per 100,000 population.

Tuberculosis and Mobilization 1940-1941

In spite of the remarkable decline in tuberculosis, the pulmonary form is still a serious menace, and more persons in the selective service age group in Massachusetts succumb to tuberculosis than to any other single cause.

*The President's Address delivered at the annual meeting of the Massachusetts Tuberculosis League, Boston, March 20, 1941.

†Fellow professor of medicine emeritus, Harvard Medical School; member, Board of Consultants on Massachusetts General Hospital.

Examination for physical fitness for service of 6,000,000 of the 16,000,000 registrants offers an unusual opportunity for tuberculosis case finding and control on a large scale. It should eliminate those unfit for service from this cause, and through discovery and treatment should safeguard the health of the individual and protect his family and the community.

Once a man is in the service, there is the likelihood of activation of the tuberculosis under physical effort, and danger of spread of the disease to others in the close contact of soldiers in barracks and tents and at mess. Furthermore, the classification of pulmonary tuberculosis in military personnel as occurring in line of duty can be made with fairness only when an x-ray examination, in addition to other methods of investigation, has been made before induction and those with the disease have been rejected.

The expected rejections for tuberculosis among selective-service registrants in the United States may be roughly estimated from the 1.06 per cent rejected for this reason in Canada. There the death rate from the disease is 54.7 (Adamson¹). For the year 1939 in the United States, the death rate from tuberculosis was 46.6, suggesting that with methods similar to those used in Canada the rejections here would in general amount to slightly less than 1 per cent. Since the death rate from this cause varies from 191.0 in Arizona to 15.8 in Nebraska, the percentage will differ in the various states. There are, in addition, some doubtfully significant or suspicious lesions that should later be re-examined. Among other disturbances to be expected, in rare cases, are cysts, polycystic disease, bronchial, pulmonary and mediastinal neoplasms, fibrosis, nontuberculous pneumonia and eventration of the diaphragm.

Importance of X-ray Examination

In the diagnosis of pulmonary tuberculosis, the history is important, and the physical examination should not be neglected. Progress in x-ray equipment and technic, however, is such that no examiner, however skillful, can compete with it in obtaining evidence in difficult cases for the exclusion of those with the disease.

In the use of the x-ray examination of registrants, greater reliance should be placed on standard large (14-by-17 inches) than on miniature films. Competent roentgenologists and facilities for the x-ray examination of registrants are available, and the expense involved is insignificant compared with the cost and hazard incident to admission of those with the disease into service.

In the selection of registrants for service during mobilization, examining physicians are cautioned to be extremely careful to reject those

with pulmonary tuberculosis. In the official regulations² it is stated, "The chest examination will include the usual methods of physical diagnosis, *supplemented, whenever indicated, by radiographic* and laboratory studies* [italics mine]."

Inadequacy of the Present Program

Routine x-ray examination of the lungs of registrants is not required before induction. The lack of general appreciation of the importance of the roentgenogram means that pulmonary tuberculosis has not been excluded in a large proportion of the men called up for service in the United States.

In the First Corps Area (including Maine, New Hampshire, Vermont, Massachusetts, Rhode Island and Connecticut), through the co-operation of the New Hampshire Tuberculosis Association, the New Hampshire Department of Health, the Adjutant General and the federal military authorities, New Hampshire has led the way in the x-ray examination of men called into service, Burroughs and Frechette⁴ reporting that between September 16 and 26 all officers and enlisted men of the National Guard and candidates for enlistment had an x-ray examination of the chest.

In Massachusetts, through the co-operation of the Massachusetts Department of Public Health and the Army Medical Corps, an x-ray examination has been made of most of the national guardsmen and of the selective-service registrants, when they appeared before the induction boards.

Throughout the First Corps Area the x-ray examination of men called up for service has been carried out in five of the states under the auspices of the state departments of health, assisted in New Hampshire and Vermont by the state tuberculosis associations. In Connecticut it has been carried out under the auspices of the State Tuberculosis Commission.

Not all members of the National Guard inducted into service had chest x-ray examinations, since some had already been inducted into service before the program was under way. In one state, sufficient funds were lacking. In another, chest x-ray studies were made only when it seemed necessary.

Selective-service registrants in the First Corps Area have had an x-ray examination at the time of their appearance before the induction boards. In two states, the x-ray films were developed and read on the day of induction. In one, some, but not all, of the films were interpreted before induction, and in three states none of the films were interpreted before enrollment into service.

From the experience in the New England states,

*X-ray machines, for use in connection with the photography of the fluorescent-screen image on a 4-by-5-inch film, have been ordered by the United States Army.

it is evident that the program has suffered from failure to make plans in advance of mobilization to include and provide funds for a chest x-ray examination as a routine, and to require that registrants be found free of pulmonary tuberculosis by this means before induction into service.

As a result of postponement of the x-ray examination until appearance before the induction boards, those rejected are likely already to have made plans for enrollment, and if there is delay in reporting positive x-ray findings on an otherwise qualified registrant, the man is already in service and may have to be recalled from some distant point.

Recommendations of the National Tuberculosis Association

At the meeting of the Board of Directors of the National Tuberculosis Association on February 15, concern was expressed regarding the lack of adequate provision for excluding pulmonary tuberculosis from the United States Army. A resolution was unanimously adopted that in the opinion

of the board it is highly undesirable to induct men with pulmonary tuberculosis into the Army of the United States and that an x-ray examination of the chest is necessary to exclude the disease. The board makes an urgent appeal that all volunteers and prospective recruits be examined by this means and be found free of pulmonary tuberculosis before induction.

To accomplish this purpose, the orders should come from Washington, and arrangements should be made by local boards for x-ray study at the time of examination. If this study must be delayed until the registrant appears before the induction boards, enrollment into service should be postponed until the result of the x-ray examination is known.

PARATHYROID ADENOMA*

Report of Three Cases

ROBERT C. COCHRANE, M.D.

BOSTON

THE following histories of three proved cases of parathyroid adenoma are presented as illustrating the symptoms, findings and some of the difficulties encountered in diagnosis, operation and postoperative treatment of this condition.

CASE REPORTS

CASE 1. L. O. (B. C. H. 657465, referred by Dr. Joseph H. Shortell), a 30-year-old woman, entered the hospital on December 16, 1931, complaining of a dull pain in the left thigh of several months' duration. She walked with a marked limp, and there was a tender area over the left sacroiliac joint.

X-ray examination showed an area of destruction in the outer aspect of the left ilium, and multiple areas in the right ischium and pubis. There were several punched out areas in the skull and mandible. Similar punched out areas, with irregularity of outline, were seen in both tibiae, the left fibula and both humeri. The spine was normal.

A tentative diagnosis of multiple myeloma was made, but the pathological report on a biopsy from the left tibia showed a tumor of the giant cell class, the suggestion

was made to study the parathyroid function. The blood calcium at this time was 9 mg., and the phosphorus 22 mg. per 100 cc.

In February, 1932, after further x-ray studies, the diagnosis of osteitis fibrosa cystica was made, and Dr. Soma Weiss, with parathyroid dysfunction in mind, put the patient on a high calcium diet, with viosterol in large doses. After 4 weeks, x-ray films showed marked bone regeneration in the previously rarefied areas of the pelvis. The patient was discharged from the hospital on a high-calcium diet, and an x-ray film the next month showed the defect in the right ilium to be entirely filled with solid bone.

She was readmitted to the hospital on May 13, because of a pathological fracture of the upper third of the left femur. The blood calcium was 13 mg. and the phosphorus 41 mg. per 100 cc. (Fig. 1). On June 14, her neck was explored and a search made for a parathyroid tumor. None was found, but two small masses thought to be parathyroid glands were removed. Only one of them proved to be parathyroid tissue. Following the operation the patient developed secondary anemia and sustained a pathologic fracture of the left humerus. The cortex of all the long bones at this time was almost paper thin (Fig. 2).

On July 7, a second exploration of the neck was made, and the left lobe of the thyroid gland was removed. No parathyroid tissue was found. The blood chemical find

Inadequacy of the Present Program

Routine x-ray examination of the lungs of registrants is not required before induction. The lack of general appreciation of the importance of the roentgenogram means that pulmonary tuberculosis has not been excluded in a large proportion of the men called up for service in the United States.

In the First Corps Area (including Maine, New Hampshire, Vermont, Massachusetts, Rhode Island and Connecticut), through the co-operation of the New Hampshire Tuberculosis Association, the New Hampshire Department of Health, the Adjutant General and the federal military authorities, New Hampshire has led the way in the x-ray examination of men called into service, Burroughs and Frechette⁴ reporting that between September 16 and 26 all officers and enlisted men of the National Guard and candidates for enlistment had an x-ray examination of the chest.

In Massachusetts, through the co-operation of the Massachusetts Department of Public Health and the Army Medical Corps, an x-ray examination has been made of most of the national guardsmen and of the selective-service registrants, when they appeared before the induction boards.

Throughout the First Corps Area the x-ray examination of men called up for service has been carried out in five of the states under the auspices of the state departments of health, assisted in New Hampshire and Vermont by the state tuberculosis associations. In Connecticut it has been carried out under the auspices of the State Tuberculosis Commission.

Not all members of the National Guard inducted into service had chest x-ray examinations, since some had already been inducted into service before the program was under way. In one state, sufficient funds were lacking. In another, chest x-ray studies were made only when it seemed necessary.

Selective-service registrants in the First Corps Area have had an x-ray examination at the time of their appearance before the induction boards. In two states, the x-ray films were developed and read on the day of induction. In one, some, but not all, of the films were interpreted before induction, and in three states none of the films were interpreted before enrollment into service.

From the experience in the New England states,

*X-ray machines, for use in connection with the photography of the fluorescent-screen image on a 4-by-5-inch film, have been ordered by the United States Army.

tion as a result of kidney damage and infection was to be expected

This case well illustrates the difficulty of finding parathyroid tumors, or even normal parathyroid glands. A persistently careful exploration of the neck at the first operation in the usual location of parathyroid glands, the retro-tracheal and esophageal areas and the mediastinum proved fruitless. Only one of the two masses removed from the right side of the neck proved to be parathyroid tissue. Inasmuch as the tumor was subsequently found within the thyroid gland on this side, presumably all parathyroid tissue was removed from this side, yet no glands were

examined. The blood showed calcium 118 mg, phosphorus 20 mg, nonprotein nitrogen 20 mg, blood sugar 87 mg, cholesterol 128 mg and phosphatase 206 (Bodansky) units per 100 cc (Fig 3). X-ray examination showed degenerative cystic changes of both tibiae and patellae and of the pelvis, ribs and skull. A biopsy specimen from the right tibia showed osteitis fibrosa cystica, with osteoid formation in part and benign giant-cell tumor elsewhere.

On June 9, the neck was explored through the usual collar incision. The pretracheal muscles on the right were divided between clamps, and the right thyroid lobe freed and rotated toward the mid line, exposing a tumor the size of a large olive on its posterior surface amid terminal branches of the inferior thyroid artery. It was yellowish brown. A portion was removed for diagnosis, and a frozen section showed a parathyroid adenoma.

About three fourths of the tumor was resected, and the wound closed without drainage. The portion removed weighed 55 gm, and the estimated weight of the tumor itself was 75 gm. Twenty-four hours after the operation the blood calcium had dropped to 10 mg, the phosphorus to 17 mg and the phosphatase to 86 units per 100 cc. The calcium reached its low point of 7.3 mg on the 3rd day. The phosphorus steadily rose until it was normal. The phosphatase remained elevated for some time.

The convalescence was uneventful, save that on the 4th postoperative day there were mildly positive Chvostek and Trousseau signs. These disappeared under treatment in 4 days.

On August 15, the blood calcium was 9.8 mg, the phosphorus 4.1 mg, and the phosphatase 47 units per 100 cc. Subsequent check-ups have shown the blood chemical findings to be normal. The patient is symptom free, and the bony defects have recalcified.

Comment. The blood chemical findings and bone picture in this patient were typical. The tumor was readily located, and its appearance was such that it could not be mistaken for any other tissue. The tumor was not entirely removed because I wished to avoid the severe symptoms of tetany encountered in Case 1, and believed that if necessary more could be easily removed later because of its accessibility. Fortunately, the amount resected proved sufficient.

CASE 3 F K, a 68-year-old man who worked as a foundry foreman, entered the Faulkner Hospital on December 26, 1939, having been referred by Dr. Gerald L. Doherty. Three weeks before admission his right hip was injured by the premature closing of a street-car door. The hip was painful, but he managed to get about. He thought it to be rheumatism, and consulted an osteopath. Four treatments aggravated the pain. He was then seen by Dr. Doherty, who diagnosed the case as a fracture of the neck of the right femur, and sent him to the hospital. The diagnosis was confirmed by x-ray study, and the previous history was suggestive of a pathologic fracture. The patient was well until September, 1938, when he fell and fractured his right clavicle. This healed within a month. In January, 1939, he again fell and fractured the neck of his left humerus. This also healed promptly. In May he fractured the neck of his right humerus. All these fractures healed rapidly, and in none was an x-ray film taken.

His general health had been excellent save for the fractures. He had lost 10 or 12 pounds in the year preceding entry.

The reflexes were normal. The heart was somewhat

FIGURE 3 Laboratory Data in Case 2

found in the left thyroid lobe removed at the second operation, and none were found on post mortem examination. The question arises whether this patient had only two parathyroid glands, or whether both surgeon and pathologist were incapable of identifying them.

CASE 2 C R J (B C H 900326), a 39-year-old man, entered the hospital on May 26, 1938, because of rheumatic pain in both knees for 2 years, which was aggravated by climbing stairs. Six months before admission, his left knee became swollen and painful. This gradually subsided, but was followed by a swelling below the right knee.

Examination showed a hard, slightly tender mass about 8 cm long and 4 cm wide on the anterior surface of the right tibia in the upper third. There was no limitation of motion in the joint. Physical examination was otherwise negative.

enlarged to the left, but the sounds were of good quality. There were no murmurs. The lungs were clear save for rales at both bases. The liver edge was four finger-breadths below the costal margin and not tender. There was no edema. The prostate was small and nontender. There was a deformity of the outer third of the right clavicle, and also a deformity of the right hand in the 3rd metacarpophalangeal joint. The right leg was shorter than the left; the foot was everted, with an overriding of the shaft of the femur on the neck. The spine was normal. The blood pressure was 156/90.

Three days after admission extensive x-ray examinations showed: old fractures of the left 7th and 8th ribs posteriorly, and of both humeral surgical necks and both clavicles; a recent fracture of the neck of the right femur;

FIGURE 4. Laboratory Data in Case 3.

a questionable incomplete fracture of the neck of the left femur; slipping of the 5th lumbar vertebra forward on the sacrum with hypertrophic changes; cystlike cavities in lower ends of the femurs, with decalcifications; generalized osteoporosis, with coarseness of bone trabeculations suggestive of a metabolic disease; a question of stone in the right kidney; and cystic areas in shafts of both humeri, the upper end of the right radius and both tibias. A diagnosis of osteitis fibrosa cystica was made.

The blood calcium was 11.6 mg., the phosphorus 2.6 mg., and the phosphatase 13.3 (Bodansky) units (Fig. 4).

On January 9, 1940, x-ray study of the gastrointestinal tract was negative. X-ray films of the chest showed the transverse diameter of the heart to be 13 cm. The left ventricle was slightly prominent, and the aorta elongated and tortuous. In the right upper mediastinum, extending as low as the aortic arch, was an oval mass 4 by 6 cm. (Fig. 5). The trachea was displaced to the left by the mass, which lay on the right of and posterior to the trachea. The trachea was slightly narrowed at this point. The mass moved with the trachea on swallowing. The appearance was that of an intrathoracic goiter, but the question was raised as to its being a parathyroid tumor.

On January 13, the thyroid gland was exposed through the usual collar incision. The pretracheal muscles on the

right were divided between clamps. Both superior and inferior thyroid arteries on the right side were ligated, and the right lobe was rotated medially. Continuous with the lower pole was an intrathoracic mass the size of a plum, which was easily delivered from the chest. The tumor was brownish and appeared to be an enlarged

FIGURE 5. Case 3.

This is a spot film of the mass on the right of the deviated and compressed trachea.

parathyroid gland that had migrated downward from its normal location near the lower pole of the thyroid gland to lie posterior to the trachea. The mass was excised, and a frozen section showed it to be a parathyroid adenoma. The mediastinum was drained and the wound closed. The pathological report was as follows: The specimen was an ovoid nodule 5 by 2.5 by 3 cm., weighing 25 gm. (Fig. 6), which by microscopic examination proved to be a parathyroid adenoma.

On the 6th postoperative day the blood calcium reached its lowest level, 6.0 mg. per 100 cc.; the phosphorus was 2.6 mg. It was probable that this level had been reached

FIGURE 6. Case 3.

The tumor mass after surgical removal.

by the 3rd postoperative day, since at that time the patient became very irritable, nervous and apprehensive. On the 5th day, although Chvostek and Trousseau signs were absent, he developed a tremor and muscular twitchings. The positive signs developed in about a week. He de-

veloped bladder tetany, had to be catheterized and was eventually put on constant drainage. A high nonprotein nitrogen was improved by forcing fluids, and as soon as the chlorides were normal, the saline solution was changed to glucose. At this point, on the advice of Dr Joseph Aub, the patient was given a much larger dose of calcium and parathormone, and from then on steadily improved. By the end of the 2nd week, he had been taken off constant drainage, was able to void, was sitting up in a chair and had recovered his usual cheerful disposition. The parathormone had been decreased, and he then was given dihydrotachysterol (A T 10).

He was discharged from the hospital February 8, much improved. Recalcification of his bones was beginning to be evident by x-ray films. Further x-ray study on May 10 showed still further recalcification. The dihydrotachysterol was discontinued in May, and in August the hip was solidly united and the patient was back at work.

Comment. This patient was considerably above the average age for this disease. It is remarkable that he could have sustained multiple fractures in a 2 year period without x-ray check up and without the suspicion that pathologic fracture might have arisen. The bone and blood picture was typical. The location of the tumor was uncertain, although the intrathoracic tumor suggested that a parathyroid gland had descended into the chest with the lower pole of the thyroid.

When the large parathyroid tumor was delivered it was deemed best to remove it entirely, because its uncommon location would have made a secondary operation hazardous. Also the trachea was deviated and constricted and it was necessary to remove this source of pressure.

The immediate drop in calcium and phosphorus was characteristic. The postoperative symptoms, as anticipated were rather severe and prolonged, but eventually recovery was complete. The patient required a great deal of treatment, and his kidney function was much impaired in the early part of the postoperative course. This patient showed the shadow of a probable stone in the right kidney. Dihydrotachysterol was very useful and was continued for 4 months before his calcium balance was completely re-established.

SUMMARY AND CONCLUSION

Three proved cases of parathyroid adenoma together with their significant findings are reported.

In two cases, the tumor was found in an unusual location. Both patients had evidence of impaired renal function and kidney stones.

The uneventful convalescence and recovery of a patient with a large adenoma in a normal position suggests partial resection rather than complete removal as the operation of choice.

319 Longwood Avenue

DISCUSSION

Dr EDWARD D. CHURCHILL, Boston. Dr Cochrane has presented us with three museum pieces of parathyroid disease, scientifically studied and skillfully handled from the surgical point of view. There are so many aspects that might be discussed that I shall very rigidly confine myself to a few notations about the operative management.

The first problem in parathyroid surgery is to find the tumor. Dr Cochrane and I were talking last night about

the psychologic state of the surgeon toward the end of the second hour of a search for a parathyroid tumor, and the necessity at that time of having a positive diagnosis to stiffen his courage. A similar psychologic state is met when one faces the necessity of operating for the second, third or fourth time on a very sick patient. Hyperparathyroidism is a diagnosis that cannot be disproved by surgical dissection. Even if four normal parathyroid glands are found there may be a fifth somewhere in a remote region of the mediastinum that cannot be reached.

A large mediastinal tumor may be demonstrated by esophageal deformity with a swallow of barium. Tumors of the posterior mediastinum are usually large and are apt to be anchored in the neck by an attachment in the region of the inferior thyroid artery. Those in the anterior mediastinum represent an embryologic descent or an origin from one of the lower branchial clefts. It is the anterior mediastinal tumor that is most likely to give the greatest surgical difficulty. If the tumor is large it can be delivered as a substernal goiter is delivered, but there is no chance of reaching or palpating a tiny fragment of soft tissue that is low. The only answer to this problem is a manubrium splitting incision that affords direct visual access to the anterior mediastinum. Here again one has to be backed up by a positive diagnosis.

Dr ERNEST M. DALAND, Boston. I should like to call attention to an article in a recent number of the *British Journal of Surgery*. The writer noticed that in some cases of parathyroidism, both when the tumor had been removed and when it had not there had not been proper regeneration of the bone around the cyst. He devised a scheme of using aluminum acetate in large quantities, given by mouth and reports a large number of cases in which he has had prompt regeneration of the cysts in cases in which they had failed to regenerate following the customary therapy.

The mechanism apparently is such that the acetate salt combines with the phosphates forming aluminum phosphate. This allows the calcium to be deposited. The author mentioned above has also used this in a number of cases of rheumatoid arthritis which he considers to be a dysfunction of the parathyroid glands with excellent results.

Dr JOHN HOMANS, Boston. Of course the fascinating side of this technical procedure is the discovery not only of the tumor itself but also of the other parathyroid glands. A good deal of stress has been laid by Dr Cochrane and Dr Churchill on finding these tumors well inside the mediastinum. As a matter of fact during the third hour of a search for one of these tumors while I was hopefully opening the jaws of a hemostat here and there over the operative field having looked behind the trachea and esophagus I happened to insert and open my snap at the junction of the superior thyroid artery with the external carotid and there at the apex—of course the superior thyroid artery slants rather downward—was a good sized parathyroid tumor.

The tendency is to look downward whereas this time the tumor was in an unusually high position.

Dr COCHRANE (closing). What interested me in the first patient was that after I had presumably removed all the parathyroid glands on the right side, and had apparently missed the parathyroid glands when I took out the left lobe of the thyroid the pathologist at post mortem could find no remaining parathyroid tissue. It raised the question whether the patient actually had four parathyroid glands or only two or three.

I want to emphasize again the point Dr. Churchill brought out about the psychologic handicap to the surgeon in the cases in which one has the typical bone picture but not the typical blood chemical findings. After one has searched for two hours unsuccessfully, in an atypical case, there is a doubt in one's mind whether to go on and subject the patient to any more search.

Dr. Lahey called me the day before yesterday to say

he was sorry he could not come to discuss the paper. He told me that he had just operated on a patient who, he was absolutely convinced, had a parathyroid adenoma, but that he had failed to find the tumor. Previously three excellent surgeons had explored the neck without success. This emphasizes the fact that it is an extremely difficult thing to find the parathyroid glands, even when one is positive that a tumor is present.

STAPHYLOCOCCAL TRACHEOBRONCHITIS TREATED WITH SULFAMETHYLTHIAZOLE AND SULFATHIAZOLE

Report of Two Cases

MAURICE H. SHULMAN, M.D.

SALEM, MASSACHUSETTS

EACH of the recent developments in the field of chemotherapy has been followed by a flood of confusing reports and claims. Sulfamethylthiazole and sulfathiazole have been no exception. A survey of the literature shows consistently good results obtained in staphylococcal infections.

Bacteriologic experiments conducted by Rake and McKee¹ have shown sulfamethylthiazole and sulfathiazole to be particularly effective. This is further substantiated in a report by Krock and Chamberlain.²

Many different types of staphylococcal infections have been successfully treated with these drugs. Grulee and Mason³ report excellent results in cases of furunculosis in children. Fitch⁴ obtained noteworthy results in a case of epidural abscess with septicemia and pyemia due to *Staphylococcus aureus*. Another case of staphylococcal septicemia, with excellent end results following the use of sulfamethylthiazole, is reported by Carroll et al.⁵

In a study of the literature one is immediately aware of the many toxic effects of these drugs. Pepper and Horack⁶ report the formation of concretions in the renal tubules following sulfathiazole therapy. Knoll and Cooper⁷ also report clinical urolithiasis due to sulfathiazole. Haviland and Long⁸ report conjunctival and scleral reactions in the course of such therapy. Further study of these reports reveals that the aged are more susceptible to these toxic effects than patients in the younger age groups.

The two cases reported in this communication throw light on the use of sulfamethylthiazole and sulfathiazole in staphylococcal laryngotracheobronchitis. The former was originally supplied by the Winthrop Chemical Company for experimental purposes only, but was then withdrawn from the market because of reports of toxic effects; the lat-

ter was used in the second case. The initial dosage of both drugs in these cases was $1\frac{1}{2}$ gr. per pound of body weight, given in four doses. The daily dosage thereafter was 1 gr. per pound of body weight.

CASE REPORTS

CASE 1.* A 2-year-old girl was admitted to the Salem Hospital in February, 1940, after an illness of 3 days. She had had malaise and hoarseness, with some fever, at home. Hoarseness became progressively worse, and the patient developed cyanosis during a coughing spell. Breathing became more labored, and the patient was hospitalized.

The family history was noncontributory. The patient was the only living child. At 3 months of age she developed mild eczema, which was much less intense on admission. The developmental history was normal. The patient had received injections of Sauer's vaccine, but no other immunizations had been performed. The present illness was the first real illness that the patient had had.

On entry physical examination revealed an acutely ill girl, who was markedly apprehensive and restless. The lips and nailbeds had a grayish, cyanotic tinge. There was some inspiratory difficulty, with slight substernal retraction. The respirations were noisy and wheezy. The tonsils were reddened, but no membrane was present. Auscultation of the chest revealed harsh rhonchi and sibilant and sonorous rales at both bases. The remainder of the examination was negative.

A diagnosis of laryngotracheobronchitis was made, and the patient was seen by an otolaryngologist. Expectant treatment was immediately instituted. This consisted of a croup tent and careful use of Sodium Amytal for restlessness. Throat smears revealed gram-positive organisms, tentatively called pneumococci, and sulfapyridine by mouth was given. Early in the morning of the day following admission, the patient had a choking spell and became cyanotic; the respirations were shallow and labored. A Mosher lifesaver was passed, and an emergency tracheotomy was done. Throat culture taken at entry grew a pure culture of *Staphylococcus aureus* (hemolytic). Sulfamethylthiazole was started with a Levine tube. For the next 7 days, the patient had a stormy course. The tracheotomy tube frequently became plugged up by thick, yellowish

*Reported through the courtesy of Dr. Robert T. Moulton.

crusts. The temperature varied from 101 to 105°F. The respirations remained about 40.

For 5 successive days the patient had a positive blood culture for *Staph aureus*. The blood level of the sulfamethylthiazole was kept between 3 and 5 mg per 100 cc. On the 5th day of medication, a morbilliform rash appeared. This was considered to be a drug rash and subsided in a few days. Several blood transfusions were given. Sulfamethylthiazole was discontinued slowly. The urine showed a positive culture for *Staph aureus* at one time, and frequently showed red blood cells and white blood cells in the sediment.

The tracheotomy tube was removed on the 17th day, after which the patient did very well. The wound healed rapidly, and the patient was discharged recovered on the 23rd day following admission.

Case 2. W. M., a 1-year-old boy, had been very well until June 22, 1940. At that time the patient was first seen at home, and a diagnosis of "croup" was made. He became progressively worse, and breathing was much more labored. Failing to respond to routine treatment the patient was admitted to the Salem Board of Health Hospital.

The family history was not remarkable except for marked allergy. One brother, 4 years old, had had severe eczema. The feeding history was uncomplicated except for slight eczema, which cleared up when the patient was put on an evaporated milk formula. The developmental history was normal. The patient had received Sauer's vaccine and diphtheria toxoid.

At home the patient had a temperature of 100°F by rectum, and respirations up to 40 per minute. No cyanosis was noted until entry on June 24. He was quite restless. At the onset of the disease, the patient had some inspiratory difficulty and no substernal retraction. Inspiration became more difficult, and the substernal retraction very marked. The chest was clear to auscultation. The throat and tonsils were red. The remainder of the physical examination was negative.

On entry to the hospital, a diagnosis of laryngotracheobronchitis was made. Because of progressive difficulty in breathing, in addition to the appearance of cyanosis, an otolaryngologist saw the patient immediately on arrival at the hospital. Tracheotomy was done at once. When the larynx was opened, the patient coughed up several large plugs of pus and immediately fell asleep. Culture of these plugs grew a pure culture of *Staph aureus*, which was slightly hemolytic.

A tracheotomy tube was secured in situ, and the patient was placed in a steam-filled room. As soon as reports of the throat cultures were obtained, he was started on sulfathiazole. Repeated blood cultures were negative. Several cultures taken from the tube grew *Staph aureus* with hemolysis in pure culture.

For 4 days after tracheotomy was done, the temperature remained about 103°F, the pulse 150, and the respirations about 40. The course was quite stormy, and several times

the tracheotomy tube became obstructed by thick plugs of mucus.

On the 5th day, the urine sulfathiazole had reached a level of 30 mg per 100 cc, and the temperature and respirations became normal. The pulse remained about 120. Convalescence was much smoother after the 5th day, but plugs of mucus collecting in the tracheotomy tube continued to be very troublesome and required constant watching.

Sulfathiazole was gradually withdrawn and finally omitted on July 7, after 14 days of administration. The temperature, pulse and respiration did not rise above normal. The hemoglobin never fell below 60 per cent, and the red cell count was never below 3,340,000. With administration of iron by mouth, the hemoglobin was 80 per cent and the red cell count 4,000,000 on discharge.

On July 8, 15 days after insertion, the tracheotomy tube was removed, with no ill effects. The wound healed rapidly, and the patient was discharged recovered on July 14, exactly 3 weeks after tracheotomy was done.

SUMMARY AND CONCLUSION

The literature on sulfamethylthiazole and sulfathiazole is reviewed. Special emphasis is placed on the toxicity of these two drugs, the former having been withdrawn from the market by the manufacturer.

Two cases of staphylococcal tracheobronchitis necessitating tracheotomy are reported. The first case was associated with a staphylococcal bacteremia, hitherto nearly 100 per cent fatal. In both, staphylococci were recovered in pure culture from the throat or coughed up plugs.

The value of sulfamethylthiazole and sulfathiazole in combating staphylococcal infections is thus substantiated by the successful outcome of these two cases.

MEDICAL PROGRESS

PLASMA PROTEINS IN HEALTH AND DISEASE*

ROBERT F. LOEB, M.D.†

NEW YORK CITY

ONE hundred and fourteen years ago, Dr. John Bostock,¹ chemist and physiologist of Guy's Hospital, studied urine and blood from Richard Bright's dropsical patients. In addition to his classic observations on the characteristics of the urine, Bostock reported to Bright, "I think I may venture to say, that the serum generally in these cases contained less albumin than in health, although I am not able to state precisely the amount of this difference." Thus, in 1827, a disturbance in the normal pattern of the serum proteins was established as a chemical characteristic of a diseased state.

In the field of immunology, von Behring² demonstrated in 1890 that the injection of attenuated diphtheria toxin into animals resulted in the formation of antitoxin in the serum, which could be employed for preventive or therapeutic inoculations. Since these immune substances are now known to be modified serum globulins, the practical as well as the theoretical importance of the serum proteins in the field of immunochemistry becomes obvious.

In 1896, Starling's³ simple and yet decisive observations on the relation between the hydrostatic pressure in the capillaries and the osmotic pressure of the serum proteins gave rise to a now familiar physiologic concept of extraordinary importance. Although Starling's work is well known, I cannot resist quoting some of the conclusions drawn by him on the basis of his experiments. He measured the return of fluid to the blood stream following the perfusion of edematous limbs, and correlated the relation of the hydrostatic pressure in the capillaries with the effective osmotic pressure of the serum proteins, which he measured directly. Starling wrote:

At any given time there must be a balance between the hydrostatic pressure of the blood in the capillaries and the osmotic attraction of the blood in the capillaries for the surrounding fluids. With increased capillary pressure there must be increased transudation—with diminished capillary pressure there will be an

osmotic absorption of salt solution from the extra vascular fluid. . . .

The significance of these representative contributions from the field of clinical medicine, immunology and physiology is apparent. Nevertheless, Morawitz,⁴ who himself developed in 1906 the technic now termed "plasmapheresis" for the study of the regeneration of serum proteins, wrote in 1909, "Many studies of blood serum in various disease conditions are on record . . . but little of importance to pathology and physiology has been gained." Our ignorance of many elementary facts concerning the serum proteins even today is great, yet this need not be a cause for discouragement. Few problems have sustained the interest and engaged the investigative activities of physicists, chemists, immunologists, physiologists and clinicians more than those concerning the serum and plasma proteins. The progress made in recent years concerning the nature of the plasma proteins, their source, their regeneration, their abnormalities in various diseased states, the physiologic disturbances attendant on their depletion, as well as their therapeutic value in the correction of certain physiologic disorders, is truly gratifying. It is toward certain aspects of this progress that I desire to draw attention in this review.

STUDY OF THE NATURE OF PLASMA PROTEINS

One of the ultimate aims of the chemist is to identify beyond question the nature of a substance by means of establishing its structure. In the field of protein chemistry, this aim is yet to be attained. This is true even though the percentages of various amino acids present in many proteins are well established and many of the linkages of amino acids and peptides have been recognized through the work of Bergmann⁵ and others in the last fifteen years. Thus, although insight into the complex structure of the protein molecule has been gained by means of these studies of the action of various enzymes on synthetic and known substrates, the groupings that lead to the specific characteristics of proteins remain obscure. The difficulties in solving the problems of the chemistry of the proteins center about the enormous com-

*From the Department of Medicine and the Department of Neurology, College of Physicians and Surgeons, Columbia University, New York City. Read before the American College of Physicians, Boston, April 23, 1941.

†Professor of medicine, College of Physicians and Surgeons, Columbia University; associate attending physician, Presbyterian Hospital.

plexity of the molecules, many of which include side chains of lipids and carbohydrates. Moreover, many of the proteins undergo denaturation with even the gentlest chemical manipulation.

The chemistry of the plasma and serum proteins naturally constitutes only a special problem in general protein chemistry. In default of essential knowledge, serum proteins are today, as in the past, classified on the basis of convention. Thus the protein of the plasma or serum that remains in solution after half saturation with ammonium sulfate or is not precipitated by 21.5 per cent sodium sulfate is defined as albumin. The proteins salted out by these means are known as globulins. By using lower concentrations of salt solutions for precipitation, the globulins are subdivided into fractions termed euglobulin, pseudoglobulins I and II and fibrinogen. Salting out continues to be the accepted method for determining the presence and concentrations of various serum protein fractions. This procedure yields information that has been of immeasurable value in the practical preparation of immune serums, in the characterization of a number of diseased states to be discussed, and in the vast majority of studies devoted to the physiologic importance of the serum proteins. Nevertheless, it must be recognized that the fractions thus estimated embrace a large number of proteins with strikingly different characteristics, and that the various components often represent loose chemical combinations of two or more proteins. The true albumins have been shown repeatedly to have a molecular weight of the order of 70,000 and those of the globulins approximately 170,000.

In the last decade, three new approaches have been applied to the study of the serum proteins. These include first, the technic of ultracentrifugation, secondly, electrophoresis, and thirdly, the application of immunochemical reactions.

The ultracentrifugation method developed by Svedberg⁶ for the study of protein solutions consists in sedimenting the molecules from a solution by means of centrifuges of special construction. These centrifuges are capable of developing rates up to 200,000 revolutions per minute, and are fitted with optical contrivances making it possible to record photographically by means of various lengths of visible and ultraviolet light the rate of sedimentation of various solutes. In this way the molecular weights of one or more substances can be determined, since the rate of sedimentation is a function of the mass of the molecule and the centrifugal force. This method also offers a valuable check on the purity of a given solute,—in this view, a serum protein,—since the substances of different molecular weights will be sedimented at

different rates and different stratum of molecules appear in the photographs obtained.

The second technic, which is proving of great value both chemically and clinically in the study of serum proteins, is in reality an old one. In 1899, Hardy⁷ demonstrated the migration of colloidal particles in an electric field. This phenomenon is termed electrophoresis. The method was later successfully employed by Michaelis⁸ to distinguish certain enzymes and proteins by their mobilities and their isoelectric points. This electrophoretic technic, which is in principle identical with that of measuring the mobility of ordinary ions, has been modified in recent years. Tiselius⁹ has made it possible to record accurately the rate of migra-

A = normal plasma B = plasma from a case of multiple myeloma C = serum from a case of nephrosis

tion of various proteins, and to separate these fractions for subsequent analysis by other means without altering their chemical nature by polarizing or heating currents. These measurements are made under standard conditions of pH, ionic strength and temperature. Like the ultracentrifuge, the boundary of the migrating molecules can be recorded photographically, employing what is known as the Toepler Schlieren method. This depends in principle on the detection of "small inhomogeneities in refractive index," caused in the serum proteins by the boundaries of the various protein fractions, migrating at different velocities. Longworth et al.^{10, 11} have ingeniously modified further the method of Tiselius and of Philpot¹² for recording the velocity of migration of various solutes. From the curves obtained by his method, calculation of the concentration of various solutes is made possible, in addition to separation of these on the basis of their velocity of migration. In Figure 1 may be seen curves obtained by Longworth et al.

intake; the maintenance of nitrogen equilibrium in the fasting animal by the intravenous administration of plasma proteins; the feeding of amino-acid mixtures in amounts sufficient to maintain nitrogen balance, in which the recent work of Mitchell and his colleagues²³ demonstrates that only seven of these acids are essential in the adult rat; the intravenous, subcutaneous or oral administration of casein hydrolysates to which are added tryptophan and cystine or methionine.

In the course of plasma protein depletion, as brought about in animals either by protein starvation, the technic employed by Weech, or by plasmapheresis in dogs maintained on a low but adequate protein intake, the method used by Whipple and his associates¹⁷ for many years, the albumin fraction suffers primarily. This is particularly unfortunate for physiologic reasons. If protein depletion has been of short duration, repletion is rapidly accomplished by the means of protein feeding. If depletion is of long standing, the rate of protein repletion, as shown by Weech, is at first rapid, but then the pace is slowed and months may be required to attain the original levels. This is true not only in animals but also in man. Of interest, but still unexplained, is the fact that after depletion of certain reserve stores of plasma protein, the protein-starved animal is unable to utilize effectively his remaining body protein or its disintegration products for plasma protein regeneration.

In contrast to clinical states of hypoproteinemia brought about by undernutrition and curable by the methods that have been shown to prevent hypoproteinemia, stand cases of nephrotic and hepatic hypoalbuminemia. Regeneration of plasma proteins in these cases is notably ineffective, owing to a failure of the albumin-synthesizing mechanism. Treatment with high-protein diets or protein autolysates brings about the storage of body protein without regeneration of plasma protein, particularly serum albumin.

In recent years Madden and Whipple and also Weech have shown beyond question that the type of protein fed is of considerable significance in relation to its efficacy in bringing about plasma protein regeneration—this applies with certainty to albumin, which is of prime importance. Thus, it has been shown that beef serum protein has an extraordinarily high potency value in plasma protein regeneration. Beef muscle, casein, egg white and others are of medium potency, and of low potency are gelatin, zein, dog red blood cells and so forth, as shown in Table 1. Evidence concerning globulin regeneration is still controversial and fortunately of more purely academic interest.

In summary, then, plasma protein regeneration in hypoproteinemic states resulting from under-

nutrition can be corrected by the liberal administration of protein, amino acids or protein autolysates. Furthermore, in addition to the quantity of protein, its quality has been shown to be a matter of considerable importance. Finally, in states in which hypoproteinemia appears to be associated, at least in part, with a disturbance in serum albumin synthesis, administration of protein may

lead to storage of body protein, with little if any increase in the serum protein concentrations.

DISTURBANCES OF SERUM ALBUMINS AND SERUM GLOBULINS IN DISEASED STATES

Modern medicine owes to a New York clinician, Dr. Albert Epstein,^{24, 25} a great debt. His studies made between the years 1912 and 1917 on the disturbances of the serum proteins in disease and his application of the Starling hypothesis in the explanation of nephrotic edema served as a great stimulus for the mass of clinical investigation in this field in the past twenty-five years.

In the normal adult, the concentration of the serum proteins varies between 6 and 8 gm. per 100 cc. The proteins determined in the albumin fraction vary between 4 and 5.5 gm., and the globulins fluctuate between 1.5 and 2.5 gm. as measured by the three methods previously discussed. It has been customary in the past to lay great emphasis on the ratio of albumin to globulin. This tradition finds its origin in the work of Epstein. He pointed out in 1912 that the decrease in serum proteins in the nephrotic state did not result from hemodilution because, if this were so, the albumin globulin ratio would remain constant. In reality, the albumin fraction was found to be sharply decreased, and the globulin perhaps slightly increased. Thus, a change in distribution of albumin and globulin was established. Since the physiologic and clinical consequences of disturbances in the serum proteins depend on the actual concentrations of the albumin and globulin fractions. I urge that emphasis be placed on these rather than on their ratio. This can be explained as follows. An albumin globulin ratio of 0.5 is obtained when the albumin is 1.5 gm. and the

globulin is 3 gm. The same ratio is present when the albumin is 3 gm and the globulin is 6 gm. It is obvious that the decrease in albumin is the striking feature in the first instance, and that an extraordinary increase in globulin results in the same ratio in the second instance. Certainly the physiologic, diagnostic and clinical implications are totally different despite identical ratios.

From the standpoint of the clinician, patients with disturbances in serum proteins may be separated into two categories: those in whom hypoalbuminemia and its consequences dominate the disease picture, and those in whom hyperglobulinemia is the outstanding abnormality. To this generalization may be added a corollary. Thus, abnormalities in the albumin fraction always occur in the direction of a decrease, whereas significant changes in the globulin fraction are associated with increases in these proteins. Albumin values greater than 55 gm. indicate either that dehydration or an abnormally soluble globulin is present. The presence of an abnormal globulin under these circumstances can be verified if the results obtained by the salting-out method,²⁶⁻²⁷ are compared with those obtained by the Tiselius or immunochemical techniques of analysis. Although there is a sound physiologic and chemical basis for segregation of patients into these categories of hypoalbuminemia and hyperglobulinemia, it must be recognized that an outstanding disturbance in one protein fraction is often accompanied by some change in the other. For example, the serum albumin in a patient with cirrhosis of the liver may be reduced to 25 gm per 100 cc, and at the same time the globulins may be increased to 5 gm. Or, in a patient with lymphogranuloma inguinale, as shown by Gutman et al.,²⁸⁻²⁹ the characteristic hyperglobulinemia is often associated with some degree of hypoalbuminemia.

The causes for hypoalbuminemia can be divided into three general groups: inadequate protein intake, excessive protein loss and failure of albumin regeneration. These groups of disturbances with their subdivisions are shown in Table 2.

Since the clinical importance of disturbances in serum albumin is dependent on its normal functions, these should be reviewed briefly. The serum albumin normally acts to maintain the effective osmotic pressure of the blood plasma, to maintain normal plasma volume, to serve as a source of energy in starvation, and to serve as a chemical buffer. The most important physiologic and clinical consequences of hypoalbuminemia depend primarily on a disturbance of one of these normal functions, namely, that of maintaining osmotic pressure. This activity follows from the fact that the albumin molecules traverse the capillary walls

only in small amounts under normal conditions. Although this lack of permeability is also characteristic of the globulins, they exert but one fifth of the osmotic pressure of the albumin fraction in normal serum. The greater osmotic activity of the albumins results from their smaller molecular weight and their higher concentration in the serum. The difference in osmotic activity of the

albumins and globulins in the blood is further accentuated by virtue of differences in their isoelectric points. These differences favor greater ionization and therefore greater osmotic properties of albumin at the pH of the blood.

Decreasing concentrations of albumin lead to a diminishing tendency for interstitial fluid to be brought back into the capillaries. In hypoalbuminemia, when the osmotic activity of the serum proteins at the venous end of the capillaries is less than the hydrostatic pressure, edema fluid will accumulate. This idea is in accord with the Starling hypothesis, the validity of which was established by the direct measurements of Landis.³⁰ Various workers have found that edema fluid tends to accumulate when the serum albumin concentration falls below a so-called "critical level." Thus, Moore and Van Slyke³¹ observed that edema was usually present in patients in whom the serum albumin concentration was less than 25 gm per 100 cc. In malnutrition, Bruckman and Peters³² state that edema almost always develops when the albumin falls below 3 gm per 100 cc. It is essential, however, to emphasize that other factors, such as the intake of sodium salts, the local renal factors of blood flow, glomerular filtration pressure, tubular reabsorption and tissue pressure, as well as unknown factors, may be of considerable importance. Thus, the rigid restriction of sodium salts tends to limit edema formation even in the presence of very low serum albumin concentrations. Also, striking diuresis may at times occur for

wholly unexplained reasons when the concentration of serum albumin is maintained well below the critical level.

From the foregoing discussion, it is apparent that marked hypoalbuminemia is characterized clinically by the physiologic tendencies that it may initiate. This is not true of hyperglobulinemia, the causes of which are presented in Table 3. The

heterogeneous groups of diseases in which increases in the globulin fraction of the serum occur include infections, tumors and metabolic disease. Hyperglobulinemia is also present at times in young Negroes who are otherwise apparently normal. No common underlying mechanism or mechanisms are as yet recognizable in these groups, although increases in serum globulins are often encountered in diseases in which plasma-cell reactions are prominent. The importance of hyperglobulinemia is, perforce, at the present time limited to its diagnostic value. This statement is not designed to detract from the clinical value of serum globulin determinations as an aid to diagnosis, but merely emphasizes the unsatisfactory state of knowledge concerning the physiologic interpretation of changes in the globulins. It is apparent from Table 3 that marked hyperglobulinemia, that is, values of more than 4.5 gm., occurs in but a limited number of diseased states and should therefore direct attention toward them. When hyperglobulinemia is of only moderate intensity, that is between 3.0 and 4.5 gm., the specificity of the disturbance is obviously reduced, and mild degrees of hyperglobulinemia are observed in an extraordinary variety of infections.

In addition to the diagnostic value of total globulin determinations, Gutman³³ has recently pointed out the usefulness of fractionation of the globulins. When the total concentration of globulin is increased, the euglobulin participates in the change with great regularity. In multiple

myeloma, however, the euglobulin may not exceed its normal concentration of 0.1 to 0.2 gm. per 100 cc. Thus when a moderate or marked increase in total globulin is present and the euglobulin is not increased, Gutman has shown that the diagnosis of myeloma, which is often exceedingly difficult in the early stages, becomes relatively certain.

USES OF PLASMA PROTEINS IN THERAPY

It seems appropriate to end a survey devoted to the plasma proteins with a consideration of their role in therapy. Plasma protein or serum protein transfusions are recommended today in the treatment of two disorders, namely, hypoalbuminemia and the state of shock. These protein transfusions are employed instead of whole blood because they may, at least theoretically, have a greater effect in restoring the plasma protein levels to normal, in increasing and maintaining an increase in the circulating plasma volume, in initiating diuresis in hypoalbuminemic states associated with edema by virtue of raising the osmotic activity of the plasma and thereby increasing the plasma volume, and in making available a utilizable source of energy in states of undernutrition.

In the hypoalbuminemic state dependent on inadequate protein intake, the therapeutic implication appears to be an increase in the dietary protein. When this aim cannot be achieved, the daily infusion of casein autolysates should be the next therapeutic method of choice. When these methods fail, it is probably justifiable to employ plasma or serum transfusions, but it should be emphasized from the economic standpoint that, in this type of case, plasma transfusions constitute a true luxury. The same recommendations apply to the treatment of hypoalbuminemic states due to excessive protein loss. One notable exception must, however, be made. Thus in severe burns when shock is largely dependent on acute plasma loss, plasma or serum transfusion becomes the emergency procedure of choice.

It is in patients whose hypoalbuminemia is associated with the nephrotic state that plasma or serum transfusions are most frequently recommended. The hope in plasma or serum transfusions probably arises from the sound logic of the procedure in a group of patients in whom high-protein diets and casein autolysate infusions have been notoriously ineffective in stimulating serum albumin regeneration. Dramatic diuretic results have been reported by Aldrich and his associates^{34, 35} in the treatment of nephrotic edema with lyophil serum. The experience of others has been less successful and suggests that the di-

uretic effects obtained were to be associated more with nonspecific reactions than with the concentrated plasma itself. My experience with plasma transfusions in nephrotic patients at the Presbyterian Hospital has been limited and truly disappointing. The following brief report is representative. A nephrotic boy, whose serum albumin was 1.3 gm. per 100 cc. before treatment, was given 2000 cc. of normal human plasma in the course of three days. It might have been anticipated that this amount of plasma would raise his serum albumin to at least 3.5 gm. In reality the serum albumin after three days was only 1.5 gm., and no diuresis occurred. The albumin transfused was either excreted in the urine or utilized as food, but it had none of the desired effects. Thus plasma transfusion in the nephrotic state is not so successful as has been hoped, but is well worth further trial, particularly if given in two to four times its normal concentration.

In the treatment of shock, the value of plasma and serum proteins has been demonstrated beyond question. There continues to be uncertainty concerning details of the best means of preparation, the optimal concentration for use and the relative values of plasma and serum. The fact that some disagreement and confusion exist concerning these details should in no way detract from the fundamental value of this type of therapy.

* * *

An attempt has been made to indicate the direction in which progress in knowledge of the problems of the serum proteins is being made. It is both interesting and significant that advances in understanding the physiologic aspects of these problems have developed simultaneously with the acquisition of empirical knowledge, which has, nevertheless, already been shown to have an important application in the practice of medicine. Thus knowledge of the mechanisms and diagnosis of disease has been enhanced materially.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTI-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27231

PRESENTATION OF CASE

First Admission. A sixty-year-old woman entered the hospital for study.

Approximately one year before admission, the patient was treated in this hospital for erysipelas of the face, and during the routine examination a slightly tender, hard, irregular mass was palpated in the mid-epigastrium; it did not move with respiration. A gastrointestinal series revealed no evidence of intrinsic disease in the esophagus, stomach or duodenum. An extrinsic pressure defect on the medial side of the stomach corresponded to the mass felt through the abdominal wall. This mass was believed to be the left lobe of the liver, although the organ as a whole was not enlarged; the spleen was small.

Second Admission. A year passed before the patient again entered the hospital for an investigation of the mass. She had lost 6 pounds during the preceding few months, but even leading questions failed to uncover any subjective symptom.

On examination the patient was well developed and well nourished. The heart and lungs were normal, the blood pressure 160 systolic, 80 diastolic. The abdomen was soft, and an orange-sized, hard, nontender mass was palpable in the umbilical region, with its lower border on a level with the umbilical line. It was freely movable and moved with respiration. The right kidney was palpable; the liver was not.

The temperature, pulse and respirations were normal.

Examinations of the urine, stools and blood were negative. The nonprotein nitrogen of the blood serum was 20 mg. and the proteins 6.5 gm. per 100 cc.; the blood Hinton reaction was negative.

A gastrointestinal series showed a normal esophagus. The stomach was elongated and low in position but showed no defects, and the duodenal cap and loop were not remarkable. The palpable mass lay medial and posterior to the upper stomach, producing a pressure defect on the posterior wall at the junction of the upper and middle thirds. There were many small gallstones and one larger stone, apparently in the cystic duct.

A barium enema passed readily to the cecum and entered the terminal ileum. The colon showed a few diverticula in the region of the sigmoid, but otherwise was not remarkable. The palpable mass lay above and medial to the splenic flexure.

An operation was performed on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD L. YOUNG: Our problem is the diagnosis of a mass that is known to have existed for at least a year in a woman of sixty and to have grown during that period without affecting her general health or causing any subjective symptoms. The possibilities of a mass in that region come down to a definite number. The mass was apparently retroperitoneal and outside the gastrointestinal tract, according to the x-ray evidence. That leaves us with the possibility of a retroperitoneal tumor of lymphoid origin, a tumor coming from the left kidney or adrenal and a tumor of the pancreas. From the description, it should not have been from the liver, for instance an echinococcal cyst or an abnormal left lobe, and it should not have been from the spleen. The spleen was noted as being normal the previous year. I am sorry that there is no note in this record about whether the mass went through to the flank on palpation. This always suggests a kidney tumor. I think that the feel of a tumor such as this helps very much in connecting it with the kidney. Nothing abnormal was found in the urine. Moreover, there is no evidence of any study of the urinary tract, and we may therefore assume that the examiners were fairly sure that the mass was not renal in origin.

The question of pancreatic tumor comes up. The pancreas is a retroperitoneal fixed organ. When this mass was first felt, it was described as irregular but not movable. Of course the question of movability of a pancreatic tumor depends on the part of the pancreas from which it arises, and whether or not it is in contact with the liver, which must move on respiration. The commonest tumor of this size in the pancreas is, of course, a cyst, probably of the tail of the organ. It could move with respiration, but I must confess it is not usual.

Was it possibly a cyst of mesenteric origin? It could not be an omental cyst, of course, and make a defect in the posterior wall of the upper medial part of the stomach. I suppose it is possible for a cyst of the mesocolon to develop in such fashion as to make a defect as described in the x-ray report. That would be more freely movable than a pancreatic cyst.

Without getting any help from the x-ray findings, but merely going on what is given here, it is a little difficult for me to make a differential diagnosis between a cyst of the mesentery and a pancreatic cyst. Pancreatic cysts are very uncommon. Up to 1936,—I think I looked them up at that time,—there had been only 5 in sixteen years at the Massachusetts General Hospital. I believe the Mayo figures were more than 80 cases out of 750,000 patients, so that it is not common. Mesenteric cyst likewise is not common, and my belief is that they do not show themselves to be quite so large as this mass was. I should like to "stick my neck out" and say this is a pancreatic cyst first, in spite of the movability. Mesenteric cyst is second. I do not believe it is connected with the kidney or adrenal, and I do not believe it is connected with the liver. I should like to allow myself a chance to change my opinion after Dr. Holmes clears everything up.

DR GEORGE W. HOLMES: Unfortunately, the evidence that I have here does not clear anything up. As a matter of fact, all one can be certain about is that there is nothing wrong in the stomach. I should think the description would lead you to suspect that the man who examined the case thought the tumor was in the region of the pancreas.

DR YOUNG: Of course the thing to do, if it is a pancreatic cyst, is to take it out if possible. Such cysts may be simple; they may be malignant. Even if they are simple, they may have to be marsupialized because of the impossibility of taking them out. If they are malignant, the effort should certainly be made to remove them.

CLINICAL DIAGNOSIS

Carcinoma of the gall bladder.

DR YOUNG'S DIAGNOSIS

Pancreatic cyst

ANATOMICAL DIAGNOSIS

Papillary adenocystoma of the pancreas

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY. This patient was operated on by Dr. Claude E. Welch, who split the gastrocolic omentum and came immediately down on a cystic structure. He was at first unable to decide which organ it was attached to, but it proved fairly readily mobilizable, and when he brought it farther up into the wound it became clear that it was attached to the pancreas. He was able to remove it without too much difficulty, and then found that in doing so he had completely

removed the middle section of the pancreas. He therefore went back and removed the distal fragment of the pancreas, to be on the safe side. This distal fragment was atrophied, and when it was cut across, a widely dilated pancreatic duct was found, with practically no recognizable pancreatic tissue. Microscopic sections showed total atrophy of the acinar cells, but the islands were perfectly preserved. It was exactly equivalent to the type of atrophy that develops from ligation of the pancreatic duct in an experimental animal. The cyst itself was 6 cm in diameter and was multilocular, consisting of multiple cavities varying from pinpoint in size up to a centimeter or more in diameter. In a great many of these cavities, papillary projections were found, and we must classify this definitely as a neoplasm, a papillary adenocystoma of the pancreas. Whether it is benign or malignant is a little difficult to be sure of. We have seen one case of this sort, which Dr. Young perhaps remembers, since it was his originally, of frankly malignant papillary carcinoma of the pancreas. That recurred after a considerable interval, seven years, I believe. This tumor in comparison looks much less malignant. I think it is quite possible that the patient was cured, but I should not be surprised at a delayed recurrence.

DR YOUNG: This interests me, because when you reviewed the slides of the original case you believed it was papillary cystadenoma and non-malignant. It was first reported as malignant, and the patient did well and apparently was cured. It recurred six and a half years later, and she died seven and a half years after the original operation.

CASE 27232

PRESENTATION OF CASE

A forty three year-old housewife entered the hospital complaining of abdominal pain.

The patient had felt perfectly well until one year before admission, when she noticed that she was becoming pale, rather weak, tired easily and was slightly dyspneic on exertion. No localizing symptoms appeared until three months before admission, at which time a sharp pain developed in the right upper quadrant of her abdomen, radiated to the right shoulder blade, and was aggravated by breathing and lying on her back. Shortly thereafter, the pain also included the epigastric region, and six weeks later it developed in the left lower quadrant, where it was stabbing in character and slightly increased by respiration. The pain became constant, and the patient went to bed suffering from anorexia and a considerable increase in exertional dyspnea. One month before admis-

sion, a loss in weight was first noticed and, in addition, an increase in the size of her abdomen. The husband believed the patient to be a little jaundiced, but no color change was noticed in the stools or urine. Two and a half weeks before admission, examination showed an enlarged liver and spleen. Gradually her dyspnea became more marked, and the right upper-quadrant pain exaggerated. One week before entry the patient was admitted to another hospital, where x-ray films were taken. At no time had there been nausea, vomiting, cough, urinary changes or vaginal bleeding. She had lost 20 pounds in weight.

The patient's father had died of carcinoma of the esophagus. The past illnesses were noncontributory.

On examination the patient was flushed and appeared chronically ill, and there was evidence of recent weight loss. The heart was normal, the blood pressure 130 systolic, 80 diastolic. At the left lung base, there were diminished excursion, slight percussion dullness and diminished breath sounds. The abdomen was distended and tympanic, and an occasional peristaltic sound was heard. No shifting dullness was elicited. A tender edge, believed to be liver, was felt in the right upper quadrant and in the epigastrium. The spleen was not palpable, but percussion dullness over the region of the spleen could be made out. Rectal and pelvic examinations were negative.

The temperature was 99°F., the pulse 100, and the respirations 30.

The urine showed a + test for albumin, with an occasional white blood cell per high-power field and many bacteria in the sediment. The blood showed a red-cell count of 3,300,000 with a hemoglobin of 10.9 gm. (photoelectric-cell technic), and a white-cell count of 8600 with 82 per cent polymorphonuclears. A blood film showed considerable marrow activity with increased platelets, some shift to the left in the polymorphonuclears, stippled and polychromatophilic red cells and a few immature unidentified cells. The nonprotein nitrogen of the blood serum was 27 mg. per 100 cc.; the blood Hinton reaction was negative. The stools were normal.

X-ray films of the gastrointestinal tract taken in another hospital were interpreted as showing flattening of the greater curvature of the stomach due to pressure from what was believed to be an enlarged spleen. The stomach emptied in six hours; the colon was low and atonic. A barium enema revealed no significant findings. With a Graham test no dye entered the gall bladder. The genitourinary tract was normal.

A flat plate of the abdomen taken in this hospital showed a large collection of gas in the left

mid-abdomen having the shape of the stomach antrum. There also appeared to be some gas-filled loops of small bowel in the mid-abdomen, but no dilated loops were visualized.

An electrocardiogram showed sinus tachycardia, low voltage in QRS, left-axis deviation and total inversion of Lead 3. T₁ and T₂ were tall and upright, and T₃ was inverted. Lead 4 was normal, save for low diphasic T waves.

On the third hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: It seems to me that the man who operated on this patient was a far better diagnostician than I am, or that he had some information I do not know of. I should not know what in the world to operate for. Here is a woman of forty-three, with pallor, weakness and slight dyspnea on exertion, who tired easily. Sometimes in carcinoma of the stomach or cecum there is such severe anemia that the patients get short of breath and have the other symptoms that go with inadequate oxygenation of the tissues. But that is not an outstanding surgical symptom. The patient was evidently not well for a long period, but nothing definite came into the picture until three months before admission, when she had sharp pain in the right upper abdomen radiating to the shoulder blade, aggravated by breathing and by lying on her back. I suppose that means something, but I cannot figure it out. Another point that is intriguing and confusing to me is that the pain became constant in the left lower quadrant, and that the patient went to bed suffering from anorexia and considerable increase in exertional dyspnea. She had had weight loss and possibly a little jaundice; there was no suggestion of it on physical examination. She had increase in the size of her abdomen. She is said to have had a palpable spleen two and a half weeks before admission, but x-ray films taken on the outside were essentially negative. I think it might be best to see the x-ray films now.

DR. GEORGE W. HOLMES: I am afraid that I am not going to help you. At first glance, one wonders how they could interpret this shadow as gas in the stomach. These films, I presume, were taken with the patient lying on her back. It is hard to tell. The striking thing is that there is no gas in the upper abdomen. One cannot see the diaphragm. If I could tell you whether the fundus of the stomach was displaced forward or backward, it would help a great deal in deciding whether the mass was liver or spleen. It must be either a very large liver or spleen or a very large mass.

Dr. McKITTRICK: In addition to what Dr. Holmes has said, we learn from the record that the patient has a positive Graham test. I am trying to find a surgical lesion, but not with much success. She may or may not have had gallstones. Certainly, they are not what she came into the hospital for. Apparently she had a large liver, and presumably a large spleen. That again is against a surgical lesion of a primary nature. The discomfort she had was certainly not characteristic.

In summary, we have a forty-three-year-old woman who had symptoms that went back a year, beginning with pallor, weakness, fatigue, and dyspnea on exertion. Three months before admission, pain came into the picture. The patient was distended, had supposedly a large liver and a large spleen, and her gall bladder did not fill. What this elaborate report on the blood means, I am ashamed to say, I do not know. I shall have to disregard it. The heart was normal on physical examination, and, Dr. Bland tells me, essentially normal in the electrocardiogram. Therefore, the dyspnea on exertion was probably not due to any heart abnormality. This woman, I believe, had either biliary-tract or neoplastic disease. It seems to me that neoplasm along the gastrointestinal tract has been reasonably well excluded by x-ray study. Carcinoma of the pancreas one might consider because of the steady constant pain that she had when she entered the hospital. The large spleen is not very satisfactorily explained on that premise, although I have seen large spleens from metastasis secondary to carcinoma of the pancreas. The distention, I suspect, was due to fluid in the abdomen, in addition to an excess of gas such as one sees in carcinomatosis or in cirrhosis. The rectal examination was negative. In other words, no nodule was felt in the pelvic floor. Somehow, I am inclined to believe that this may well not have been a carcinomatous mass with a carcinomatosis. I suppose one always has to consider, in the presence of unexplained abdominal findings, the question of Hodgkin's disease with involvement of the liver and of the spleen and possibly with retroperitoneal glands. I do not believe that the patient had a surgical lesion. I am going to put as my first impression cirrhosis of the liver, although there is nothing in the record to warrant any suggestion as to its etiology. The second guess that I can make would be a malignant lymphoma, and from there on it would be an open field.

Dr. EDWARD L. YOUNG: Do you think peritoneoscopy would have helped?

Dr. McKITTRICK: I think it would have been a great deal of help.

Dr. WILLIAM B. BREED: I should like to ask Dr. Richardson about the blood.

Dr. WYMAN RICHARDSON: I looked at the blood. May I read my notes? I saw the patient a short time before the answer was discovered and made the following notes:

The abdomen is very much distended and tympanitic. I cannot make out any large amount of fluid. There is no general glandular enlargement. Blood smear shows considerable marrow activity, with increased platelets, some shift to the left of polymorphonuclears; stippled and polychromatophilic red cells and a few very immature and unidentified cells are present. The clinical and blood picture, to me, rules out cirrhosis of the liver and Banti's disease (thrombosis of the splenic vein). The most probable diagnosis is malignant disease of some sort, with "myelophthisic" anemia most probable. Leukemia is not excluded. There is a question of intestinal obstruction. I have considered tuberculosis, but this is not likely. Further study should include a flat plate of the abdomen, peritoneoscopy and possibly bone-marrow biopsy if no definite diagnosis is established.

I might say I thought before this problem was answered that the patient had carcinoma of the pancreas, with metastases. I should like to add one word: A blood picture that shows this amount of marrow activity with immature red cells and immature white cells is not compatible with anemia from cirrhosis of the liver or even from hemorrhage. It means, then, some active marrow disease, and it is not infrequently seen in severe neoplasm, especially when the liver is very much involved.

CLINICAL DIAGNOSES

Malignant disease.
Myelophthisic anemia.

Dr. McKITTRICK'S DIAGNOSES

Cirrhosis of liver.
Malignant lymphoma.

ANATOMICAL DIAGNOSES

Carcinoma of gall bladder, with extension to liver and metastases to lung, hepatic, retroperitoneal and bronchial lymph nodes.
Pulmonary collapse, lower lobes, bilateral.
Ascites.
Arteriosclerosis, aortic and coronary, slight.

PATHOLOGICAL DISCUSSION

Dr. TRACY B. MALLORY: I think possibly the statement in the record that operation was performed is misleading. The operation was peritoneoscopy. Dr. Edward B. Benedict is not here to describe his findings, but it was obvious at a glance that the liver was filled with metastases.

The patient rapidly failed and died. At the time of autopsy, the entire upper abdomen was filled with liver. There were 5 kilograms of it. The spleen was not significantly enlarged, weighing 270 gm., which is not palpable enlargement. The particular portion of the liver that was most enlarged was the left lobe, and it was unquestionably that which was felt and interpreted as the spleen. The enlargement of the left lobe I am sure was quite sufficient to account for the abnormality on x-ray examination. The gall bladder at first glance seemed normal, although a little dilated. The anterior wall was thin. When it was cut into, it contained a large amount of clear, colorless fluid. On the posterior wall, in the bed adjacent to the liver, was a fungating cauliflower mass. This unquestionably was a primary carcinoma of the gall bladder that extended directly into and almost completely replaced the liver. The amount of liver parenchyma left was under 500 gm., I should think.

DR. McKITTRICK: Dr. Holmes really gave away what he had in the back of his mind. He gave me quite a tip-off when he stressed the density

in the upper abdomen, because it would be quite hard to explain the combination of that density with the location of the gas bubble on any other basis. Do you ever get as large a liver as that in either cirrhosis or lymphoma?

DR. MALLORY: Yes; in both. Five kilograms of liver are not extremely rare in early stages of alcoholic cirrhosis.

DR. McKITTRICK: Do you usually get a diffuse enlargement, or is it apt to be more or less localized to one lobe?

DR. MALLORY: That is unusual in cirrhosis, but is certainly not uncommon in cancer.

DR. McKITTRICK: I think I should have done better with Dr. Holmes's interpretation of the x-ray films.

DR. RICHARDSON: And the blood smear.

DR. HOLMES: If you could have been sure that the fundus of the stomach was displaced backward instead of forward, you could be certain it was liver and not spleen.

DR. MALLORY: I agree with Dr. Richardson's point. The blood picture was an excellent lead.

THE CLOSED-STAFF HOSPITAL

It was not very long ago—about the turn of the century—when those members of the public who required more than office care from their physicians or surgeons turned away with suspicion whenever hospital care was suggested. This attitude, doubtless, was only a later expression of the justifiable fear that existed in the "Sairy Gamp" era when hospitals were either poorhouses or institutions for the insane and those suffering from chronic alcoholism. Brought up to date, this fear expressed itself in terms of dread of "unnecessary cuttings," "experimentation by students" and the like. It forced the members of the medical profession to compromise their ideals and to care for their major obstetric, medical and surgical problems in private homes, pending education of

the public to the advantages of hospitalization. Thanks to the advancement in the science as well as the practice of medicine, the increased use of hospitals as teaching centers, the development of new ideas in the management and training of the house staffs in the hospitals but, most of all, to the mental acuity of the patients and their families, this education was sufficiently far advanced so that hospitalization was not only accepted but demanded by seriously ill patients at the time of the outbreak of World War I.

With this increased use it was shortly apparent to the profession that there were illegitimate as well as legitimate advantages to having a hospital to call on. Such evils as therapy—particularly surgical—without diagnosis, inadequate and incompetent medical care, the blocking rather than the facilitation of post-mortem examinations, the neglect of records, with resulting medicolegal complications and injustices, and many unethical financial arrangements between unscrupulous physicians and surgeons became commonplace and were rapidly undoing all the educational good that had been accomplished with so much effort.

Some disciplinary measures were essential. Because the surgeon had the greater and more dramatic opportunity to fall by the wayside, corrective action was first taken by this branch of the profession. This led to the formation of the American College of Surgeons. Over the intervening years since its organization, this and other societies—backed by the financial support of an enlightened public—have evolved a method whereby a maximum of control is exercised over those persons and tendencies in the medical profession that consciously or unconsciously threaten to bring back the evils mentioned above. This has been accomplished by keeping the services rendered by both the hospitals and the visiting staffs at the standard that is acceptable to the majority of doctors. Such hospitals as meet these standards are rewarded by certification of acceptability. This is inevitably followed by an improvement in the caliber of their resident staffs, an easing of their financial burdens through willingness of patients to pay more and promptly.

and an encouragement to their trustees in obtaining public support for their efforts to protect the local communities.

Furthermore, this certification leads to the requirement of the hospital that the work and medical morals of the visiting staff be kept at a high level. To accomplish this the hospitals—for their own self-protection—have created the closed-staff and courtesy-staff organization and denied to such members of the medical profession as were either unwilling or unable to conform to the minimum standards set up by the American College of Surgeons and other analogous institutions the right to practice or care for patients within their walls. Those physicians and surgeons who are allowed membership on such closed or courtesy staffs are universally favorable to the arrangement and rightly jealous of their professional and ethical standards. In the light of the present-day attitude of the public, as represented by their financial support of such hospitals, by their patronization of such staff members and by their demand for such facilities in cases of serious illness, it is apparent that this movement meets with the approval of the intelligent part of the patient population.

Physicians and surgeons who have not been granted these privileges are prone to cry favoritism, graft in high places, coercion and so forth. They either ignore or know nothing of the historical background that led to the present-day arrangement. In particular they fail to recognize that any member of the medical profession, regardless of the school from which he graduated or the societies to which he belongs, who can demonstrate to fellow members in his community, and to the trustees of the hospital that serves his community, that he is technically equipped, adequately trained, ethical and desirous of keeping constantly up to date in his profession will have no difficulty in obtaining permission to practice in his local hospital, even though it is inspected and certified as meeting the minimum requirements of the American College of Surgeons. They must not forget that such certification has the actual or implied support of the American Col-

lege of Physicians, the American Hospital Association, the American Nursing Association, the American Red Cross and similar organizations. Attempts to camouflage inadequacy, incompetence or lack of ethics under the specious plea that membership in a state medical society automatically negates the considered judgments of the doctors peers are doomed to failure and are indefensible.

X-RAY EXAMINATION OF RECRUITS

It seems quite clear from the article on "Tuberculosis and Mobilization" in this issue of the *Journal* that the National Tuberculosis Association has made significant recommendations regarding the elimination of tuberculosis in those selected for service in the forces of the United States. It has recommended that Washington order x-ray examination of the lungs to be carried out by the local selective-service boards, thus rooting out tuberculosis at the source, with a consequent saving of time and money. Secondly, it points out that if examination is put off until the appearance of the candidate before the induction board, enrollment into the service should be delayed until the result of the examination is known. Both recommendations are sound.

It is pertinent to consider what x-ray technic is best suited for such a survey of recruits. Miniature films are becoming increasingly popular in mass-survey work. The 35-millimeter and 4-by-5-inch films are both photographic reproductions of the image thrown on a fluoroscopic screen, and the procedure is known as fluorography. The initial cost of equipment is high, but the cost per picture very low,¹ being at least one tenth that of the standard 14-by-17-inch film. But factors other than expense influence the decision of the best technic.

It has recently been shown that in carefully studied series of x-ray examinations 4-by-5-inch films failed to reveal 2.6 per cent of the cases of tuberculosis diagnosed by means of standard films.^{2,3} In a survey of a million recruits, assuming the incidence of tuberculosis to be 1.0 per cent, examination by the miniature film on this

basis would fail to show 260 small lesions in the lung. The small lesion that is unrecognizable by physical examination presumably represents active tuberculosis, and is therefore potentially a source of danger to the candidate as well as to those associated by contact with him. Further research will undoubtedly perfect the accuracy of the miniature film, but so long as an error of 2.6 per cent persists in the hands of competent observers its adoption as a weeding-out procedure does not seem justified.

Spillman⁴ has shown how the eventual cost of missed cases of tuberculosis in World War I has mounted to hundreds of millions of dollars. Since standard x-ray films remain the final word in the diagnosis of pulmonary disease not detectable by the usual physical examination and since most radiologists are not familiar with the interpretation of the miniature reproductions, the chest examination of all recruits by means of 14 by-17 inch films cannot be too strongly urged, in spite of the apparent economy of miniature films.

MEDICAL EPONYM

HOFFMANN'S ANODYNE

Originally one of the secret remedies that Friedrich Hoffmann (1660-1742) dispensed for a consideration, this mixture gradually became a universal pharmacopoeial and popular medicine. The following translated quotation is from the second edition of Hoffmann's *Medicinae Rationalis Systematicae [Theory and Practice of Medicine]* (Vol. III, Sect. II, p. 533, Frankfurt, 1738), "wherein are set forth the true fundamentals of therapy, the process of healing, laws of nature and of medical science, as well as select remedies."

To be sure, I too have resorted fairly frequently to the use of correct opiates. But ever since the fortune of heaven bestowed on me the discovery of this penetrating and pleasant smelling liquid,—with its aromatic taste and odor, formed from a portion of vitriol of sulfur (which, indeed, was used even by chemists of old as an anodyne), by a special chemical formula of preparation,—I have refrained from all others. Now this liquid, which I am accustomed to denote by the

name of liquid mineral anodyne, is formed from sulfur alone. It burns rapidly and fiercely and is consumed, and criches fire very quickly from the flame of a candle even when held away from it a distance of three fingers, and in a warm room it evaporates speedily, yet to the touch it is very cold, just like ice, and when thoroughly distilled and purified it floats on the top of water, just like oil. The uses of this remedy are many, and its virtues varied. It is admirable for soothing pain and inducing slumber, and it is therefore used with great advantage in sharp attacks of colic, stone, cardialgia, gout or pains of head and teeth. It also starts perspiration, and although it is very heating, it does not stir up the blood. Moreover, it leaves no feeling of torpor or weakness in the head, for that reason it can be given with benefit to all invalids when their strength is at a low ebb, as in a hectic fever, and what is even more surprising, with an actual increase in their strength. Finally, because its action is first and foremost on the stomach,—in all stomach disorders, nausea, inflation, hypochondria, asthma and cardialgia,—it shows unequaled effectiveness in putting an end to flatus.

ECTOPIC PREGNANCY WITH FATAL TERMINATION

A thirty six year-old primipara began to flow thirty five days after a normal period and flowed for only two days. It was thought that her period was shortened because the patient's feet had become wet. Three days after the flow ceased, she had a severe pain in the lower abdomen, which caused her to perspire freely. She was seen by her family physician.

Examination revealed a temperature of 99.3°F, a pulse of 60 and a blood pressure of 125 systolic, 70 diastolic. The abdomen was soft and nontender. The pain was attributed to menstrual discomfort, and morphine was prescribed. Four hours later, the pain in the lower abdomen had subsided, but there was acute pain in the epigastrium. The temperature at this time was 96.4°F, the pulse 60, and the blood pressure again 125 systolic, 70 diastolic. A telephone conversation four hours later revealed that the patient had vomited and felt much better. She was seen again in four hours, when her pulse was rapid and she was in a serious condition. She was taken to the hospital by ambulance and died on arrival. Post mortem ex-

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

amination revealed rupture of the left tube and much free and clotted blood in the pelvis and abdomen.

Comment. This case emphasizes the importance of appreciating that scanty flow with abdominal pain occurring any time after the expected menstrual date may mean disease and should suggest the possibility of ectopic pregnancy. This indicates immediate pelvic examination. No vaginal examination is reported to have been made in this case. It is really inexcusable that when this patient was first seen the necessity for a vaginal examination did not become apparent. Undoubtedly had one been made, tenderness in the pelvis would have led to earlier operation. It is also difficult to believe that, in view of the amount of blood that was subsequently found in the abdomen, the initial pain in the lower abdomen, so severe as to cause perspiration, was not accompanied by tenderness and spasm. There is no medical excuse for this mistaken diagnosis and subsequent fatality.

DEATH

DOUGHERTY — HARRY L. DOUGHERTY, M.D., of Boston, died June 1. He was in his forty-third year.

Dr. Dougherty received his degree from the University of Louisville School of Medicine in 1925. He was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, his parents, two daughters, two sons, four sisters and three brothers.

MISCELLANY

SEROLOGIC TESTS FOR THE DIAGNOSIS OF SYPHILIS AND GONORRHEA

The Health Department of the City of Boston has announced that, effective June 1, the routine serologic test at the Bacteriological Laboratory for the diagnosis of syphilis will be the Hinton flocculation test. Temporarily, on request, parallel spinal-fluid and blood Wassermann tests will also be carried out. The Kahn test will be performed only when requested.

NOTE

At a meeting in Richmond, Virginia, on May 5, the American Branch of the International League against Epilepsy elected Dr. H. Houston Merritt, of Boston, president, and Dr. Frederic A. Gibbs, of Boston, secretary-treasurer, for the ensuing year.

CORRESPONDENCE

QUALIFICATIONS FOR HOSPITAL-STAFF MEMBERSHIP

To the Editor: My attention has been called to several instances in which members in good standing in our society have been refused courtesy privileges in certain hospitals. In each case the physician concerned was a graduate of a school other than Class A, according to the usual standard of classification.

The reason invariably set down for the refusal to grant such privileges is that the American College of Surgeons will not certify hospitals if graduates of such schools are admitted to their staffs.

There is within this state an ever-increasing group of these graduates who have been found qualified by the Massachusetts Board of Registration in Medicine, who have been considered capable and conscientious by the boards of censors of the Massachusetts Medical Society and who practice good medicine. This denial of hospital privileges has in specific instances not only made the paths of practice difficult for these doctors, but has brought about actual hardship, and does not seem just to me.

I am quite aware of our lack of jurisdiction over the action of the staffs of hospitals. Nevertheless I do question the wisdom of tacitly permitting practices which may at some time be held to be discriminatory, hence damaging, to exist within our membership.

When it is considered that such action as is taken is in compliance with the rule of the American College of Surgeons and that the burden is placed upon the hospital, I sometimes wonder just what the advantages of hospital membership in the college are. All this quite naturally raises the questions from whom the American College of Surgeons derives its authority and whether or not the pursuance of policies which might one day be held to be discriminatory upon the part of our membership is ethical under the standards set up by our society.

FRANK CRUICKSHANK, M.D.

Brookline, Massachusetts

NOTICES

MASSACHUSETTS INSTITUTE OF TECHNOLOGY

A program in public-health engineering, covering military and public-health practice, will be given at the Department of Biology and Public Health, Massachusetts Institute of Technology from June 16 to July 25; the program will emphasize the application of facilities in public-health engineering to industrial and military problems of the national defense preparation. Basic training in chemistry and biology is required for this program, which is intended primarily for graduate engineers, sanitary chemists and biologists, bacteriologists, officers in the United States military service and others engaged in public-health engineering work.

EVANS AUDITORIUM

The third of a series of lectures by Dr. Albert B. Ferguson on "Roentgenology of the Bones and Joints" will be delivered at Evans Auditorium, 78 East Concord Street, Boston, on Monday, June 9, at 7:30 p.m.

The medical profession is invited.

AMERICAN COLLEGE OF PHYSICIANS

The twenty-sixth annual session of the American College of Physicians will be held in St. Paul, Minnesota, on April 20-24, 1942. Dr. Roger I. Lee, of Boston, president of the American College of Physicians, will have charge of the program of the general sessions and lectures. Dr. John A. Lepak, of St. Paul, has been appointed general chairman; he will be in charge of the program of hospital clinics and round-table discussions.

as well as local arrangements. Mr Edward R Loveland, executive secretary of the college, 4200 Pine Street Philadelphia, will have charge of the general management of the session and of the technical exhibits.

AMERICAN CONGRESS OF PHYSICAL THERAPY

The twentieth annual scientific and clinical session of the American Congress of Physical Therapy will be held September 1-5, at The Mayflower, Washington, D C. Mornings will be devoted to the annual instruction course, and afternoons and evenings to scientific sessions. The seminar and convention proper will be open to physicians and qualified technicians.

For information concerning the seminar and preliminary program of the convention proper, address American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago.

At the same time, the twenty fifth annual meeting of the American Occupational Therapy Association will be held at The Mayflower. A combined meeting will be held on Wednesday, September 3. For information concerning the American Occupational Therapy Association, address Mrs Meta R Cobb, 175 Fifth Avenue New York City.

UNITED STATES CIVIL SERVICE EXAMINATIONS

Public Health Nursing Consultant, \$2600 to \$3000 a Year
Medical Technician, \$1620 to \$2000 a Year
Junior Laboratory Helper, \$1440 a Year

The United States Civil Service Commission has announced open competitive examinations to fill the positions of public health nursing consultant, medical technician and junior laboratory helper in the United States Public Health Service of the Federal Security Agency. Full information regarding the qualifications required and the applications for these examinations may be obtained from the Secretary, Board of United States Civil Service Examiners, at any first class or second class post office, or from the United States Civil Service Commission Washington, D C.

EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

The next examination for appointments as assistant surgeon (lieutenant, junior grade), United States Navy Medical Corps, will be held at all major Medical Department activities on August 11 to 15, inclusive. Applications for this examination must be received at the Bureau of Medicine and Surgery, Navy Department, Washington D C not later than July 15.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty one but less than thirty two years of age at the time of acceptance of appointment, and graduates of a Class A medical school who have completed at least one year of intern training in a hospital accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association.

A circular of information listing physical and other requirements for appointment subjects in which applicants are examined, application forms and other data pertaining to salary allowances and so forth may be obtained from the Bureau of Medicine and Surgery on request.

An examination for appointment as acting assistant surgeon for intern training in naval hospitals accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association will be held at all major Medical Department activities on June 23 to 26, inclusive. Students in Class A medical schools who will complete their medical education this year are eligible to apply for these appointments, and if successful will receive their appointments approximately one month after the date of the examinations. Students in Class A medical schools who will have completed their third year of medical education this year are eligible to take this examination, and if successful will receive their appointments on or about July 1, 1942 after they have completed their medical education.

Applicants for appointment as acting assistant surgeon for intern training must be citizens of the United States, more than twenty one but less than thirty two years of age at the time of acceptance of appointment. Acting assistant surgeons are appointed for a period of eighteen months. After the appointee has served as an intern in a naval hospital for twelve months, he is eligible for and may take the examination for appointment as assistant surgeon.

A circular of information listing physical and other requirements for appointment as acting assistant surgeon subjects in which applicants are examined, application forms and so forth may also be obtained from the Bureau of Medicine and Surgery on request.

Assistant surgeons and acting assistant surgeons for intern training are appointed in the rank of lieutenant (junior grade), United States Navy Medical Corps. The pay and allowances for an officer of this rank total \$2699 per year if he has no dependents, and \$3158 per year if he is married or has dependents.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Roentgen Interpretation. By George W. Holmes, M.D., roentgenologist, Massachusetts General Hospital, and clinical professor of roentgenology, Harvard Medical School; and Howard E. Ruggles, M.D. Sixth edition, thoroughly revised. 8°, cloth, 364 pp., with 246 illustrations. Philadelphia: Lea and Febiger, 1941. \$5.00.

Lectures on Diseases of Children. By Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., consulting physician, London Hospital and Hospital for Sick Children, Great Ormond Street; and Alan Moncrief, M.D., F.R.C.P., physician to the Children's Department, Middlesex Hospital, and to outpatients, Hospital for Sick Children, and pediatrician, Queen Charlotte's Maternity Hospital. Eighth edition. 8°, cloth, 471 pp., with 107 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.75.

Introduction to Physical Biochemistry. By J. M. Johlin, Ph.D., D.Sc., associate professor of biochemistry, Vanderbilt University School of Medicine. 8°, cloth, 231 pp., with 10 illustrations. New York: Paul B. Hoeber, Incorporated, 1941. \$2.75.

Health in Iceland. By Vilmundur Jónsson, director of public health, Iceland. A reprint from *The Report on Public Health in Iceland, 1938*. 8°, paper, 29 pp., with 3 charts and 1 map. Reykjavík: Ríkisprentsmidjan, 1941.

Physical Medicine: The employment of physical agents for diagnosis and therapy. By Frank H. Krusen, M.D., associate professor of physical medicine, Mayo Foundation, University of Minnesota, and head of Section on Physical Therapy, Mayo Clinic. 8°, cloth, 846 pp., with 351 illustrations. Philadelphia: W. B. Saunders Company, 1941. \$10.00.

A Short History of Psychiatric Achievement, with a Forecast for the Future. By Nolan D. C. Lewis, M.D., professor of psychiatry, College of Physicians and Surgeons, Columbia University, and director, New York State Psychiatric Institute and Hospital. 8°, cloth, 276 pp. New York: W. W. Norton and Company, Incorporated, 1941. \$3.00.

Handbook of Anaesthetics. (Formerly by Ross and Fairlie.) Revised by R. J. Minnitt, M.D. (Liverpool), D.A. (D.C.P. and S. Eng.), lecturer in anesthesia, University of Liverpool, director of anesthetics, David Lewis Northern Hospital, Liverpool, and honorary anesthetist, Liverpool Royal Infirmary and Liverpool Maternity Hospital. With chapters on local and spinal anesthesia by W. Quarry Wood, M.D., Ch.M., F.R.C.S.E., surgeon, Edinburgh Royal Infirmary. Fifth edition. 12°, cloth, 364 pp., with 103 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$4.00.

Hutchison's Food and the Principles of Dietetics. Revised by V. H. Mottram, M.A. (Cant.), professor of physiology, King's College of Household and Social Science, University of London; and George Graham, M.D. (Cant.), F.R.C.P. (Lond.), physician to St. Bartholomew's Hospital. Ninth edition. 8°, cloth, 648 pp., with 30 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$6.75.

BOOK REVIEWS

Surgery of Modern Warfare. Vol. 1. By sixty-five contributors. Edited by Hamilton Bailey, F.R.C.S. 4°, cloth, 480 pp., with 502 illustrations. Baltimore: Williams and Wilkins Company, 1941. \$10.00.

This is a very timely book, and will find great usefulness in training the medical personnel of our army and navy in the methods of traumatic surgery. It is written by sixty-five specialists who have had first-hand experience with the casualties of the war in England. The first part of the book is devoted to general subjects such as burns, septic wounds, prevention of tetanus and skin grafting; the second half deals with wounds in the various organs and regions of the body. The difficult problems of traumatic neurosurgery are not considered but are to be the subject of a second volume.

If a generalization on such a detailed work as this is permitted, one would say that the great advances in the present war are the routine débridement of fresh wounds, and the use of closed plaster in the treatment of compound fractures that are accompanied by widespread destruction of soft tissue. The principle that the body will handle infection in very large wounds, if allowed to do so by immobilization and closed dressing, is associated in this country with the name of Winnett Orr and in Europe with Trueta. The substantiation of this work by such a critical writer as Bailey makes it obligatory that it should be adopted in this country by all those who are called on to do war surgery.

The certainty of active immunization for tetanus is not upheld by these authors as a proved fact. They use prophylactic antitoxin whether or not a patient has had toxoid previously. This contradicts American opinion, which considers active immunity to tetanus as a very reliable procedure. The authors record a definite clinical impression about the value of x-ray in the treatment of gas gangrene. No figures are given to prove this conviction, but the impression is so favorable as to warrant its use routinely.

The book has dozens of good illustrations, some of them done in color. This would be a monumental effort during peacetime. That it was produced by busy and harassed surgeons on war duty is a great compliment to their endurance and devotion to science.

An Introduction to Dermatology. By Norman Walker, Kt., M.D., LL.D., consulting physician; and G. H. Percival, M.D., Ph.D., physician for diseases of the skin, Royal Infirmary, Edinburgh. Tenth edition. 8°, cloth, 391 pp., with 102 plates and 96 illustrations. Baltimore: Williams and Wilkins Company, 1939. \$7.00.

This small book on dermatology has numerous interesting features. The senior author, a British dermatologist of wide experience, always writes in a very personal way and delves into his past contacts with patients for many apt cases and therapeutic results. He explains the derivations of many disease names, and other such bits of information are of interest to the reader. The descriptions of disease manifestations are not so profuse as those in many textbooks, but the excellent color plates provide the student with a lifelike appearance of many skin diseases. Many types of dermatitis are quite thoroughly discussed. Therapeutic measures are based on many years' experience in clinics and private practice, and often form an interesting contrast with the usual methods in this country. Syphilis is very inadequately handled.

EQUINE ENCEPHALOMYELITIS IN MASSACHUSETTS*

An Analysis of the 1938 Outbreak, a Follow-Up of Cases and a Report of a Mosquito Survey

VLADE A. GETTING, M.D.†

BOSTON

INFECTION of man with the Eastern variety of equine encephalomyelitis was first demonstrated by Fothergill, Dingle, Farber and Connolly¹ and by Webster and Wright.² These workers isolated the virus from the brains of children who had died of a previously unrecognized type of encephalitis during an outbreak of equine encephalomyelitis in the horses of southeastern Massachusetts. Reviews of equine-encephalomyelitis infections in horses and men and the history of this disease have been made by Gordon³ and Fothergill.⁴ A description of the Massachusetts outbreak of equine encephalomyelitis, with an analysis of the cases in man, was reported by Feemster⁵ in 1938. It is the purpose of this paper to add further detail to Feemster's report, to follow up the surviving patients, and to make a report on the Massachusetts Mosquito Survey, which was organized to ascertain the distribution of mosquitoes that have been demonstrated to transmit experimentally the Eastern type of equine encephalomyelitis to laboratory animals.

THE MASSACHUSETTS OUTBREAK

In July, 1938, for the first time, equine encephalomyelitis was recognized in horses in southeastern Massachusetts; and in the course of about ten weeks 269 deaths were reported. The geographical distribution of deaths in horses is given in Figure 1. The disease made its first appearance in the upper basin of the Taunton River, which drains through nearby Rhode Island, and spread to contiguous areas, particularly toward the northeast. There were relatively few cases to the south and southeast, and none occurred on Cape Cod or the nearby islands. About 70 per cent of the Massachusetts cases occurred in a thirty mile

square, extending from the mouth of the Taunton River in the south to Boston on the north, and from the boundary of Rhode Island, eastward to the coast of Massachusetts. Isolated cases occurred as far north as Maine and as far west as Worcester. Rhode Island to the west reported 55 cases among horses, and Connecticut 29.

During the summer and early autumn, rainfall in southeastern Massachusetts and Rhode Island was unusually heavy, and as a result mosquitoes were very prevalent in these areas. The prevailing winds in this region are from the southwest, and the tendency of the outbreak to spread in a northeasterly direction may be partly explained by the supposition that infection-bearing mosquitoes were carried by these prevailing winds. Two other factors, the movement of infected horses and the flights of infected birds, probably played an important role in the spread of the outbreak. Horses that were apparently well were moved from one country farm to another, on one such occasion a horse was moved thirty miles northeast to a town near the coast. Although apparently well when moved, the horse developed symptoms on the following day, and the diagnosis of equine encephalomyelitis was proved by the isolation of the virus from the brain. During the outbreak, Fothergill and Dingle⁶ isolated the Eastern type of virus from the brains of a pigeon that had died in the same area, southeastern Massachusetts, and Tyzzer, Sellards and Bennett⁷ isolated the same virus from the brains of ring-necked pheasants from Connecticut. These findings suggested that birds may be reservoirs of the disease and factors in its spread.

Almost simultaneously, in the same area, a new type of human encephalitis appeared, largely limited to children. The geographical distribution of the cases is shown in Figure 2. This outbreak was the first known infection of man with the

*From the Division of Communicable Diseases, Massachusetts Department of Public Health, and the Department of Epidemiology and Preventive Medicine, Harvard School of Public Health and Harvard Medical School.

Eastern variety of equine encephalomyelitis virus. The prevalence of the cases among horses and human beings is given in Figure 3. The median date of reported deaths among horses occurred during the week ending August 27, or two weeks in advance of the median date of onset for cases in human beings. Apparently, the peak of the

equine encephalomyelitis. From 9 of the patients Fothergill¹ and Webster and Wright² isolated the Eastern virus. These workers established the diagnosis of equine encephalomyelitis in 10 other cases by finding neutralizing antibodies for the same virus in the blood of the patients.

Eight other cases were diagnosed on the basis

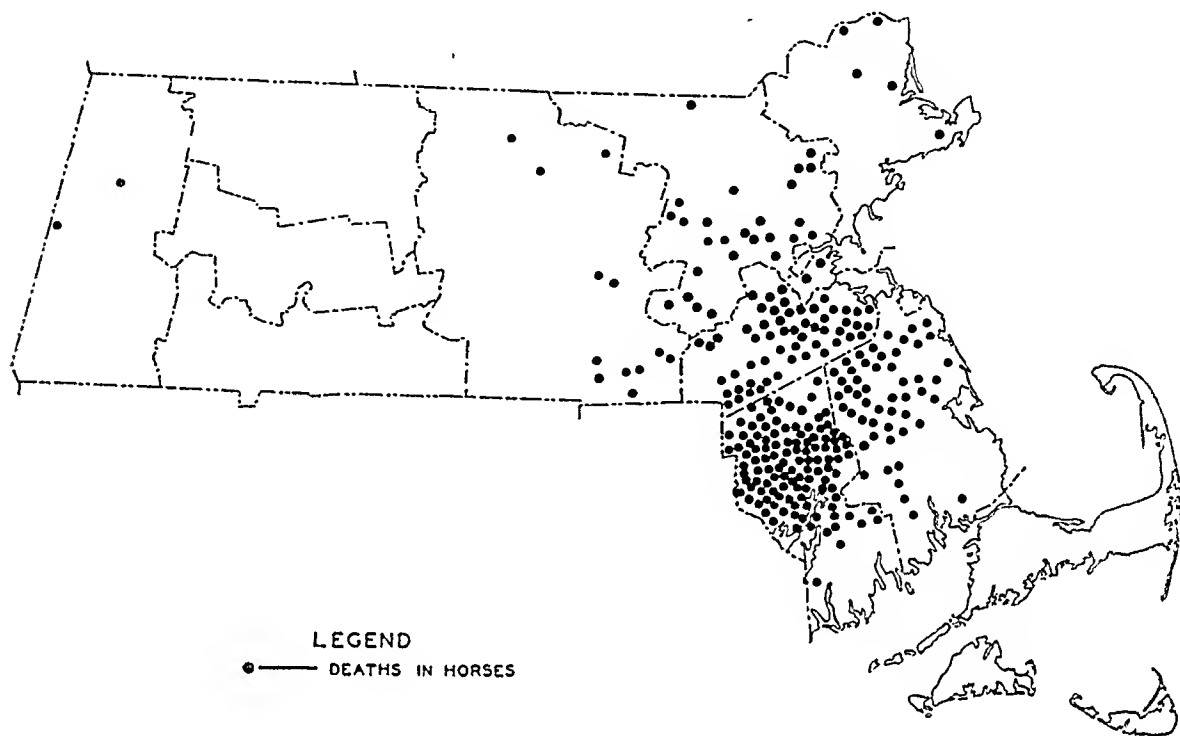

FIGURE 1. *Distribution of Equine Encephalomyelitis in Horses in Massachusetts, 1938.*

The deaths were most numerous in Bristol, Plymouth and Norfolk counties, the three counties between Boston on the north and Buzzards Bay on the south.

outbreak among horses preceded that of the outbreak among human beings by an interval of over two weeks. Although the prevalence of the disease was much greater among horses than among human beings, the rise and fall of the outbreak in these groups was similar. The epizootic began slowly without increase for four weeks, and then rapidly reached its peak in two weeks. Remaining at this peak level for about a week, the outbreak subsided more slowly than it had begun. The last case was reported late in October, sixteen weeks after the beginning of the outbreak.

There were no multiple cases among families, and multiple cases on the same farm or in the same stable were rare among horses. These field observations confirmed experimental evidence that the disease is not transmitted by contact between laboratory animals.

ANALYSIS OF CASES IN MAN

In all, the Massachusetts Department of Public Health investigated 44 cases suspected of being

of pathognomonic brain lesions at autopsy. These autopsies were performed by Wesselhoef, Smith and Branch,⁸ Farber et al.⁹ and Alexander.¹⁰ A diagnosis of equine encephalomyelitis was considered justified in 7 additional patients because of the characteristic clinical findings. These cases were fatal and were not autopsied; blood specimens for neutralization tests were not obtained. Ten other cases were suspected of being due to the Eastern virus, but investigation revealed that a diagnosis of equine encephalomyelitis was unwarranted. In all, there were 34 patients in whom the diagnosis of infection with the Eastern virus seemed justified.

In analyzing these 34 cases, 2 groups were considered.

Proved cases. This group included the 9 cases in which the virus was isolated and the 10 in which the presence of neutralizing antibodies was proved. The finding of neutralizing antibodies has been considered proof of infection with the Eastern variety virus because these persons presented the same acute disease and the same clinical find-

ings as those from whom the virus was isolated. Moreover, Fothergill⁴ has been unable to find neutralizing antibodies in the blood of family contacts of proved cases, human or equine.

The age distribution of the proved and typical cases is given in Table 1. One quarter of these patients were less than one year of age, 70 per cent were under ten years of age, and only 15

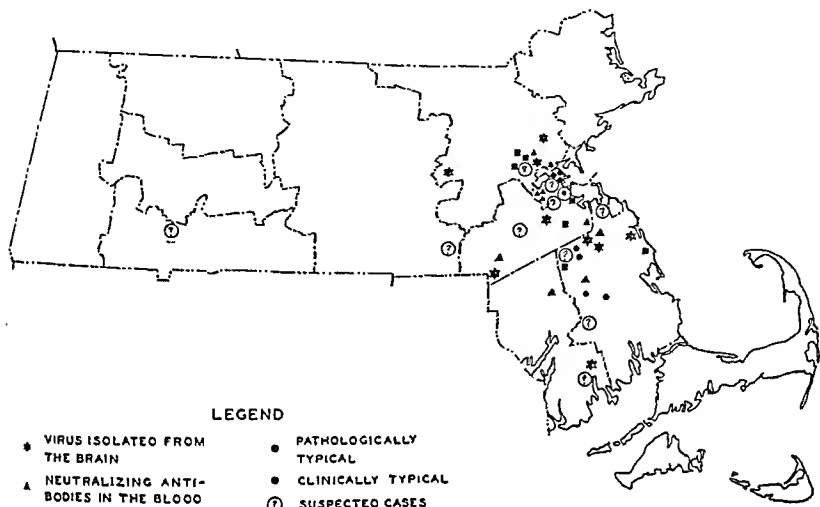

FIGURE 2. Distribution of Equine Encephalomyelitis in Man in Massachusetts, 1938.

In general, the distribution of human and horse infections corresponds. The apparent greater density of infections in Metropolitan Boston is due to the greater density of population.

Typical cases. The 8 cases in which the diagnoses were based on pathognomonic brain lesions, and the 7 in which there were characteristic clinical

per cent were over twenty-one years of age. The sex distribution was the same in both groups: 17 patients were males, and 17 were females.

The fatality rate among the 34 patients was 74 per cent. This compares with a fatality rate of

FIGURE 3. Seasonal Incidence of Equine Encephalomyelitis in Massachusetts, 1938.

The outbreak among horses was greater than that among human beings; the peak of the former preceded the peak of the latter by about two weeks.

findings comprise this group of patients. Since the diagnosis was less convincing, they are not included with the proved infections.

90 per cent among horses in Massachusetts, 94 per cent in Rhode Island and 93 per cent in Connecticut.

Wesselhoeft, Smith and Branch⁸ have reported the cases that were hospitalized at the Haynes Memorial in Boston. McAdams and Porter¹¹ described a case in Fall River, and Farber et al.⁹ analyzed the cases from the Children's Hospital in Boston. The following description of the

clinical course of this disease, as observed in Massachusetts, is based on observations of the patients and on analysis of the records of all the patients.

The disease was sudden in onset, especially in children. Following a period of prodromes associated with a fever of 100 to 102°F., nausea and vomiting, and headache in older patients, there was a period of well-being, lasting from twenty-four to thirty-six hours. During this time the temperature often dropped, symptoms disappeared, and in one case a child was well enough to go to see a motion picture. As a rule, patients did not come under medical observation until the disease was well advanced, and this period of prodromes was consequently observed in only a few cases. The acute manifestations of the disease are summarized in Figure 4. The symptoms are listed in

were frequent and often indicated the onset of convulsions. Edema, observed in infants and small children, was not pitting, and involved the extremities and face.

The duration of the disease varied from less than one day in fulminating attacks to over three weeks in the less severe forms. Table 2 gives the duration of the disease. The median length of

the order of frequency with which they were observed: high fever ranging from 103 to 106°F., drowsiness progressing to stupor and coma, convulsions, either clonic or tonic, a stiff neck, often developing into generalized rigidity or opisthotonos, nausea and vomiting, cyanosis, irritability in infants and headache in older patients. Twitchings

duration was seven days for all the cases, over twenty days in the patients who survived, and four days in those who died. Of 10 patients who lived after the tenth day of illness, 4, or 40 per cent, died. The 4 patients who succumbed after twenty-one days of illness died either of exhaustion or of intercurrent infection.

A diagnosis of equine encephalomyelitis cannot be made on clinical findings alone. Laboratory data furnish confirmatory evidence. There is a leukocytosis of 14,000 to 66,000, with a differential count of 75 to 90 per cent neutrophils and 25 to 10 per cent lymphocytes. The spinal fluid is under increased pressure, and there is a pleocytosis during the acute phase, the counts averaging 500 to 1000 cells, chiefly neutrophils, per cubic millimeter. With the subsidence of the acute phase, the spinal-fluid cell count drops, and the lymphocyte becomes the predominating cell. Spinal-fluid sugar and chlorides are at a normal level, but the total protein is increased, especially in the convalescent stage.

Although blood cultures for the virus were not obtained during the epidemic, it is likely that if they are made early, using defibrinated blood, positive cultures may be obtained. Ten Broeck, Hurst and Traub¹² have isolated the virus from the experimental disease in horses, and Howitt¹³ has reported the isolation of the Western variety from the blood of a patient. According to Fothergill's⁴ findings, neutralizing antibodies may appear as early as the first week of the disease but are not likely to do so until the second week. Complete pathological descriptions have been written by Farber and Branch.¹⁴

There is no specific therapy for equine encephalomyelitis. Treatment is symptomatic and supportive. Isolation of the patient is not necessary, since the disease is not transmitted by direct contact. Chick vaccines, effective in the immunization of horses, have not yet been developed for use in man. Moreover, they are of no value in the treatment of horses.

FOLLOW UP OF CASES

All 9 surviving patients in whose blood neutralizing antibodies to the Eastern variety of virus were found were seen at varying intervals from the date of the original illness. In all cases except one, this follow up was made approximately a year after onset. These cases have been under the care of various physicians and clinics, and this analysis is made with the permission of each. Table 3

TABLE 3 Summary of Follow Up

summarizes the observations in the surviving patients. All but 3 developed disabling sequelae. Six showed evidence of cerebral degeneration, with definite mental retardation. Three patients continued to suffer from a hemiparesis, 3 from complete or partial aphasia, and 1 from emotional instability.

At this early date it is impossible to prognosticate the eventual course of these sequelae. However, it seems not unlikely that they are permanent and may even be progressive. In encephalitis lethargica, sequelae have appeared as late as five or more years after the original illness, and it is therefore important to follow these patients for at least five years.

MOSQUITO SURVEY

As soon as the true nature of the equine encephalomyelitis outbreak was realized, the Massachusetts

Department of Public Health, with the assistance of the United States Public Health Service, undertook the organization of a mosquito survey. During August and September, 1938, mosquitoes were unusually prevalent. On September 21, a severe hurricane swept over New England and many mosquitoes were destroyed. Identification of specimens collected in October revealed *Culex* and *Anopheles* mosquitoes. *Aedes* were no longer active, and relatively few were collected.

The study of the history of equine encephalomyelitis reveals that the disease often recurs in the same region in succeeding years. Therefore, during the early months of 1939 the Massachusetts Department of Public Health, under the direction of the commissioner, Dr. Paul J. Jakmauh, began to make plans for a state-wide mosquito survey. The aims were to ascertain whether mosquitoes are the natural vectors of the disease, to find naturally infected mosquitoes and to ascertain the distribution of experimentally demonstrated vectors, so that when and if the disease recurred, control measures might be effectively and efficiently instituted.

The active work of the survey was made on a state-wide basis during the months of July, August, September and October. It was carried out in co-operation with the Work Projects Administration, which supplied a personnel of 150. This personnel was under the technical direction of a member of the Department of Public Health and ten entomologists, who were employed during the course of the survey. Almost 50,000 separate collections of mosquitoes comprising 278,000 specimens were made by the WPA personnel and volunteer collectors, who were obtained through the co-operation of the local boards of health. Various state and federal institutions, schools, summer camps and many other agencies made numerous collections of mosquitoes. It is the purpose of this paper to make a report on this mosquito survey so far as it is concerned with equine encephalomyelitis.

In all, 56 different species of mosquitoes were collected in Massachusetts. Thirty-seven of these are biting and the remainder are nonbiting. Only 6 of the biting species have been shown by investigators to transmit experimentally the Eastern virus of equine encephalomyelitis to laboratory animals. Positive experimental transmission has been carried out with the following Massachusetts mosquitoes by Davis¹⁵: *Aedes cantator*, *A. sollicitans*, *A. texans*, *A. atropalpus* and *A. triseriatus*. *A. taeniorhynchus* was not collected in numbers large enough to conduct transmission experiments, however, Ten Broeck and Merrill¹⁶ have demonstrated

that it is a laboratory vector of the Eastern variety of virus. *Culex*, *Anopheles*, *Mansonia*, *Uranotaenia*, *Wyeomyia* and other genera of mosquitoes have thus far been unable to transmit the disease to laboratory animals in experiments conducted by Davis and other investigators.

Data, collected by the survey, have furnished additional epidemiological support to the mosquito-transmission theory of equine encephalomyelitis.

Seasonal prevalence of vector and disease. For the effective transmission of a mosquito-borne disease, there must be a certain minimal numerical

quitoes in 1938 provided optimal conditions for the outbreak.

Geographical distribution. The vectors of equine encephalomyelitis were present in those areas where, formerly, the disease was present. Only two vectors, *A. vexans* and *A. triseriatus*, were present in all places where cases occurred. *A. triseriatus*, however, was found to be only one fifth to one fifteenth as numerous as *A. vexans*. Therefore, statistically, it seems that *A. vexans* is the most important vector of equine encephalomyelitis.

The geographical distribution of the vectors of

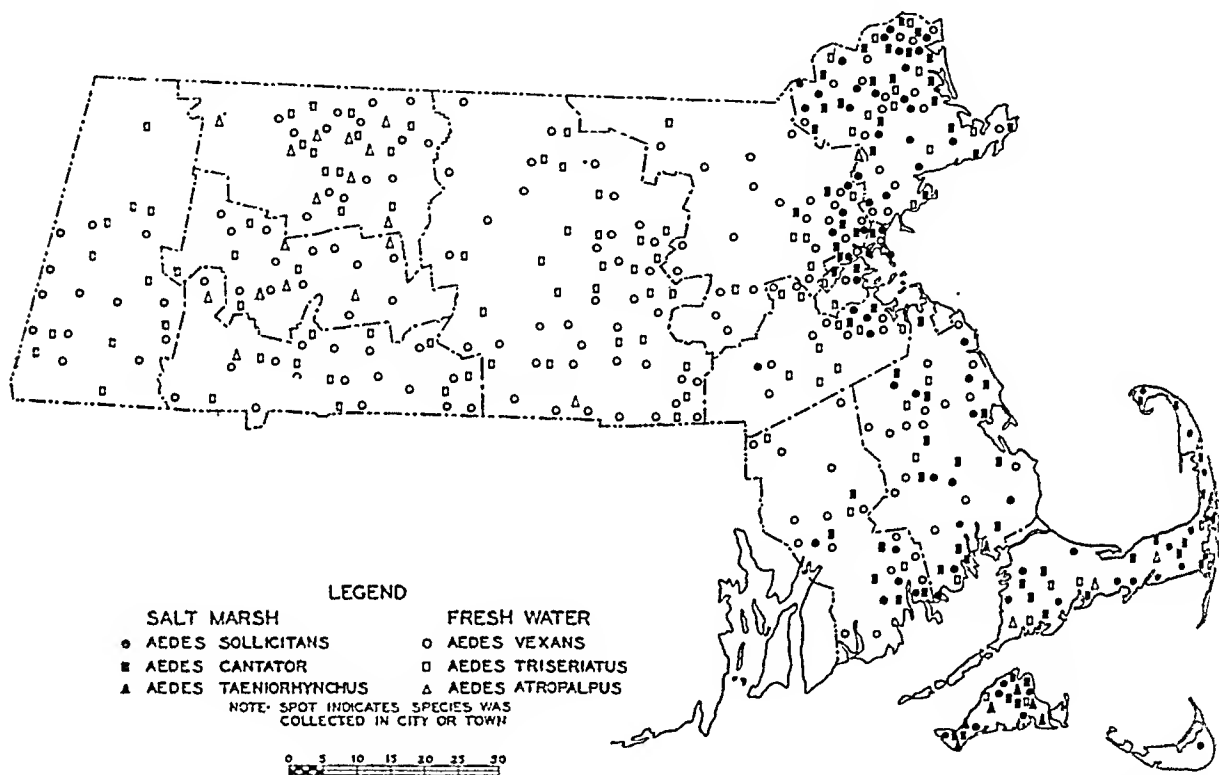

FIGURE 5. Distribution of Vectors of Equine Encephalomyelitis (Eastern Variety) in Massachusetts, 1939.

Aedes vexans was 5 to 15 times as numerous as *A. triseriatus*. The salt-marsh species were limited to an area fifteen miles from the nearest breeding place.

relation between the vector, host and susceptibles. When the vectors are unusually prevalent, conditions for increased transmission are present. In 1938, the outbreak reached a peak in late August and early September. In 1939, the seasonal prevalence of mosquitoes was determined. Whereas the genus *Aedes* was more abundant in spring and early summer, the vectors, *A. atropalpus*, *A. cantator*, *A. sollicitans*, *A. taeniorhynchus*, *A. triseriatus* and *A. vexans*, were most numerous in August and September. The seasonal prevalence of the suspected vector corresponds to that of the disease. Therefore, conditions most conducive to the transmission of the virus exist in the late summer and early autumn. The unusual abundance of mos-

equine encephalomyelitis is shown in Figure 5. *A. vexans* and *A. triseriatus* are state-wide in distribution. *A. sollicitans* and *A. cantator* are both salt-marsh mosquitoes, which are usually limited to within ten miles of the salt water, but which in exceptional circumstances may be found fifteen miles inland. *A. atropalpus* breeds in clear water that has accumulated in eroded rock formations, as in the Connecticut Valley, Essex County and Cape Cod. *A. taeniorhynchus*, which Ten Broeck and Merrill¹⁰ have shown to be able to transmit the Eastern variety virus experimentally to laboratory animals, has been collected only along the southern coast of Massachusetts — on the island of Martha's Vineyard and adjacent Cape Cod.

The most probable natural vector. Further confirmatory evidence that *A. vexans* is the principal vector is found in the distribution of equine-encephalomyelitis cases in 1939. Twelve cases in horses were diagnosed by the Massachusetts Department of Agriculture. Although most of these were diagnosed on clinical findings, the virus was isolated from the brains of two horses that had lived and died in the towns of New Braintree and Westborough. These towns are so far inland that no salt-marsh mosquitoes were collected, and the probability that a mosquito of this group infected these horses is negligible. The nearest breeding place of the salt-marsh vector was twenty miles from Westborough and over fifty miles from New Braintree. Fifteen miles away from their breeding places is the greatest distance at which the adult salt-marsh mosquitoes, *A. sollicitans* and *A. cantator*, were collected. When wind-borne, both species have been recorded to fly farther. However, the prevailing winds in the summer and early autumn blow from the west and southwest, hence the salt-marsh mosquitoes would have to fly against the wind for twenty to fifty miles to reach these two towns. Furthermore, long flights of salt-marsh mosquitoes are a rare phenomenon; statistically, therefore, the chances that a few adults may survive such long flights are almost negligible. All these facts point to a mosquito other than a salt-marsh *Aedes* as the carrier. Only two vectors were found in this area, *A. triseriatus* and *A. vexans*. Since *A. vexans* is five to fifteen times as numerous as the former, statistically, *A. vexans* is the most probable vector responsible for the infection of these horses.

Age distribution of cases according to the bionomics of vectors. The determination of the bionomics of the vectors of equine encephalomyelitis offers explanations of several phenomena observed in the 1938 outbreak. Twenty-six per cent of the cases in human beings were in infants under one year of age, and 70 per cent of the patients were children under ten. Although detailed information about individual cases has not been obtained, the high incidence among the young age groups may be explained by the following observations. During the summer, infants are often left to sleep outdoors, sometimes without protective netting, and are unable to defend themselves against mosquitoes. Moreover, children under ten who play outdoors the greater part of the day are less efficient than older groups in protecting themselves, since they do not react to a mosquito until it has bitten them. Thus infants and children who sleep or play outdoors are more apt to be bitten than older persons who, taught by experience, react to the buzzing or alighting of a mosquito.

Outdoor vectors. It was observed that horses which were kept outdoors formed the larger portion of the cases. Data collected during the survey indicate that the vectors are more likely to bite in the open than indoors. Hence, horses that are outdoors are more apt to be infected.

Of all mosquitoes captured on man outdoors, 60 per cent were vectors, whereas only 6 per cent of those caught indoors were carriers. Therefore, the chances that a mosquito is a vector are ten times as great if the biting occurs outdoors than if it occurs indoors. These findings suggest why infants and children comprise such a large number of the cases.

SUMMARY

Equine encephalomyelitis due to the Eastern variety virus infected 34 persons during an outbreak of this disease among horses in southeastern Massachusetts in 1938. Small infants and children under ten years of age constituted 70 per cent of the cases.

The onset of the disease is acute, the course rapid, and death occurs in less than ten days in the majority of cases.

Permanent sequelae occurred in 6 of the nine surviving patients. The sequelae, in the order of frequency, were mental retardation, hemiparesis, aphasia and emotional instability.

Three salt-marsh species—*Aedes cantator*, *A. sollicitans* and *A. taeniorhynchus*, and three fresh-water species, *A. atropalpus*, *A. triseriatus* and *A. vexans*, all vectors of equine encephalomyelitis—were collected by the survey in 1939. The former are usually limited to within ten miles of salt water. Two, the fresh-water vectors *A. triseriatus* and *A. vexans*, were state-wide, the latter being five to fifteen times as prevalent as the former.

A. vexans is probably the most important vector of equine encephalomyelitis in Massachusetts. Along the coast the *A. sollicitans* and *A. cantator* are about as numerous as *A. vexans* and may have been, in part, responsible for the outbreak of 1938 in the coastal region.

The epidemiologic and entomologic data collected by this survey support the laboratory evidence that equine encephalomyelitis is transmitted by mosquitoes, because the geographical distribution and the seasonal prevalence of the disease and the vectors have been found to be the same. The biting habits of the vectors of equine encephalomyelitis suggest that man and animal outdoors are exposed ten times as much to the chance of infection as those in buildings.

A FIERY ORDEAL*

JOHN FLEET, M.B.

BOSTON

I GRADUATED from Harvard College in 1785 and determined to become a doctor. I at once entered the new Medical School at the College in Cambridge, and for three years sat under those erudite young teachers, Dr. John Warren, Dr. Benjamin Waterhouse and Dr. Aaron Dexter. On May 23rd, 1788, shortly before I obtained my degree of Bachelor in Medicine at Commencement. I appeared before the Censors of the Massachusetts Medical Society in the County Court House in Boston, where meetings of the Society were held, hoping on their approval to obtain a license to practise the healing art in the Commonwealth.

The Board of Censors of the Society at the time was made up of Dr. James Lloyd, Dr. Joseph Gardner, Dr. Isaac Rand, and Dr. Samuel Danforth of Boston; and Dr. Oliver Prescott of Groton. Dr. Prescott, being hard of hearing, took no particular part in my examination; business prevented Dr. Danforth's attendance.

Dr. Lloyd was the senior member present. He ranked high in the profession in those days. He had taken the lead in regard to the practice of surgery in Boston and was the first who introduced hereabouts the male practice of the obstetric art as a general appendage to the attire of a physician. He was very successful in it and consequently was greatly esteemed among the ladies. He entertained a great deal of company, kept a genteel equipage and a suite of servants; his horses were esteemed equal to any in the town. In brief, he was a gentleman of the old stamp and deservedly respected and valued.

Dr. Joseph Gardner was employed both as a physician and surgeon as much as any other gentleman in the profession. He, too, was an older man, in practice for some years, and included among his pupils John Homans and Charles Jarvis. He pretended that he looked upon learning as superfluous; that the bedside was the only school for a physician. But he did study and was a more learned man than he chose to appear. When he wished he could be both witty and satirical.

Dr. Isaac Rand, the youngest Censor, was a pupil of Dr. Lloyd's. He acted as Secretary of the Board. He was interested in mathematics and was always seeking for something like scientific fact on which to lean in his profession. For want of knowledge he was continually dissatisfied and read more books than any physician in Boston. To be sure, he was apt to pin his faith in the last book he read; but he was a successful practitioner, had a discriminating judgment, and was remarkably neat in his operations.

These were the gentlemen who were to examine me. The examination was to be no easy task because Dr. Warren and his new school at Harvard were by no means popular with physicians of the Massachusetts Medical Society. Dr. Warren was regarded by many as an artful man who had got to the windward of his colleagues in establishing a medical school and himself a Professor. Dr. Waterhouse, in the Theory and Practice of Physic, was thought to have received his appointment in part, at least, because he was a relative and pupil of Dr. Fothergill of London; and it was common gossip that Dr. Fothergill intended to help in the development of a Medical Institution in New Eng-

*An unpublished manuscript. Submitted by Dr. Reginald Fitz.

land where his relative and student proposed to dwell, Dr. Dexter, a respectable figure, pretended to no greater knowledge of Chymistry and the Materia Medica than did several other members of the Society who also had academical leanings, so that the justification of his choice was queried. I knew, as first product of this new School to be examined by the Censors of the Massachusetts Medical Society, that I would be thoroughly sifted. And indeed I was.

Dr Rand began my examination by asking me to describe the process of deglutition and digestion.

I answered, "The food is first taken into the mouth, divided by the teeth, and pushed back wards by the muscles of the throat."

"Is there anything to prevent it from passing into the trachea?"

"The glottis." And then I added immediately, "The epiglottis, I mean, that covers the glottis."

"What is the epiglottis?"

"A cartilaginous substance."

"Proceed in the process," said Dr Rand.

"The food is pushed into the esophagus, passes down to the stomach, is then mixed with the gastric juice and operated upon by the stomach. If vegetable food be used, a fermentation takes place."

"What is the upper orifice of the stomach called?"

"Cardia."

"What the other?"

"Pylorus. The food is next protruded into the duodenum, and there it mixes with the pancreatic juice and bile."

"What conveys the bile into the duodenum?"

"The ductus communis choledochus."

"Does the hepatic duct enter the ductus communis choledochus?"

"Almost always," I answered.

"Proceed with the food," Dr Rand demanded.

"The food being mixed with the bile and pancreatic juice, of what use is the bile?"

I hesitated. He repeated the question.

"It assists to form chyle," I answered.

"Go on."

"When chyle gets into the small intestines it is absorbed by the lacteals."

"What are the lacteals?"

"Vessels that convey chyle to the receptaculum chyli."

Dr Gardner interrupted. "Where does it lie?" he asked.

"I do not exactly remember upon which vertebra of the loins," I replied.

Dr Rand resumed the questioning. "What does the chyle pass through in going to the receptaculum chyli?" said he.

"Some small glands," I replied.

"That is not what I mean. Is there nothing else?"

"The mesentery, do you mean, Sir?"

"Yes," he said. "Where does the chyle go after it enters the receptaculum chyli?"

"It passes up by the thoracic duct to the left subclavian vein and mixes with the blood, from thence it passes with the blood into the right auricle of the heart."

"What pushes it to the heart?"

"Its own contraction and the pulsation of the aorta. the thoracic duct also has valves."

"What prevents the chyle regurgitating when it enters the vein?"

"There is a valve that prevents its return."

"Proceed in the circulation."

"The blood is propelled from the right ventricle into the lungs."

"By what vessel?"

"The pulmonary artery."

"What peculiar structure has the pulmonary artery?"

"It is said to form spiral lines around the extremities of the air vessels."

There was some confusion in a question asked here, in other words, there were several statements made. One question I recollect was what effect respiration had on these spiral lines.

"They are compressed by inspiration," I replied.

"Is the blood quickened by respiration?" asked Dr Rand.

"Yes."

"How is the blood brought back from the lungs?"

"By the pulmonary vein into the left auricle, next into the ventricle, from thence it is protruded into the aorta and conveyed throughout the body. The aorta ascendens sends off the carotids and subclavians, the right carotid from the subclavian, and left from the aorta itself."

"What arteries convey the blood to the head?"

"The carotids and vertebrals."

"How do they convey blood for secretion to the brain by the dura mater or into the substance of the brain itself?"

"They are spread on the dura mater and pia mater, pass with it into the convolutions of the brain and into the cortex, and if there is any secretion they perform it."

Dr Rand now said, "Give us some account of the veins of the brain."

"They return the blood into the sinuses."

"Is there any peculiarity in the veins of the brain?"

"Sinuses are peculiar to the veins of the brain."

"Where does the blood

"The blood passes from the longitudinal sinus to the lateral ones, from thence to the base of the brain, and goes out at the jugular veins."

"What arteries enter the large foramen of the os occipitis?"

"The vertebral. They pass along a notch or hole in the vertebrae of the neck."

"How many lobes has the cerebrum?"

"Four."

"How many has the cerebellum?"

"I believe it consists but of one."

"What is the junction of the cerebrum and cerebellum called?"

"The medulla oblongata."

"What is it called afterwards?"

"Spinalis."

"What prevents one hemisphere of the brain from falling upon the other?"

"The processus falciformis."

"Where does it arise?"

"From the crista galli and proceeds along the sagittal suture."

"What are the lymphatics of the brain, is there any other system of vessels, and do the arteries terminate in them?"

"No, Sir," I answered. "The lymphatics arise from cavities, interstices of fibres and the parenchyma."

"Where do the lymphatics of the lower extremities go? Suppose a wound in a lymphatic and a virulent matter introduced, where will it appear?"

"In the groin."

"Right," said Dr. Rand. "Where do they go next?"

"They pass into the receptaculum chyli, and mix with the chyle."

"Do they come from all parts of the body?"

"Yes."

"Name the bones of the head."

"The ossa parietalia joined together by the sagittal suture, os frontis joined to the parietalia by the coronal suture, ossa temporalia by the squamous sutures, os occipitis by the lambdoidal suture, os sphenoidis by the squamous and transverse sutures and the os ethmoides."

"What bones form the orbit?"

"Ossa frontis, palatia, maxilla superioris, os planum, os unguis."

"The bones of the face?"

"I believe there are thirteen," I answered. "I have enumerated some of them."

"Proceed with the rest."

"Ossa nasi, ossa spongiosa, superior and inferior vomer, maxilla superior and inferior."

"You have omitted ossa malarium," said Dr. Rand rather coldly. "Now give the bones of the arm."

"Os humeri, radius, ulna, carpus, metacarpus, phalanges."

"What prevents the shoulders falling in?"

"Clavicula," I answered.

"To what are they joined?"

"To the sternum and scapula."

"What process has the scapula and what is its use?"

I did not readily recollect the name and he told me. Then he asked, "What are glands and their composition?"

"They are composed of arteries, veins, and excretory ducts."

"Do arteries terminate any other way?"

"They open into cavities and on the surface of the body."

"What kind of articulation is the joint of the elbow?"

"Ginglymus," I replied.

"What is ginglymus?"

"It is an articulation resembling a hinge."

"Name another instance."

I did not answer immediately. He asked what kind of joint that of the ribs was. I did not know. He said that was ginglymus.

Then he asked, "What is it blood is composed of?"

I answered, "Salt, water . . ."

He stopped me, saying that he did not want the chymical properties but the spontaneous divisions. So I replied, "Coagulum and serum."

Dr. Lloyd now interrupted and said that he supposed I knew but that I did not recollect the proper term. Dr. Rand said that I meant crassamentum, and that there was another part, too,—coagulable lymph,—which had not been mentioned. I told him this element required an operation to be recognized but he answered that it needed only a little whipping.

At about this juncture Dr. Rand was asked by the other gentlemen to desist as time was failing. So he said, "It is your turn now, Dr. Gardner, to examine the candidate in the practise of physic." After this, Dr. Rand took out his watch every few minutes and complained constantly as long as the examination lasted that time would fail unless they made haste.

Dr. Gardner began with, "What is inflammation?"

I replied, "An increased action of the vessels of any part."

"What are the causes?"

"Anything that irritates or excites the arterial system to greater motion."

"Well, suppose a man had an inflammation in his leg, what would you do?"

I made some pause until he went on, "I mean a phlegmon, I wish to be understood. What would you do?"

"I would first endeavor to discuss or resolve it."

"What are the terminations of inflammation?"

"The common terminations of inflammation are in resolution, suppuration, gangrene or mortification."

Dr. Rand interrupted. "How about fomentations?" I said I would use them also. Dr. Gardner went on. "What do you mean by emollients?"

"Such things as will take off the stricture of the vessels and allow of an effusion from them."

"What is a pleurisy? How do you know a person has got the pleurisy?"

MASSACHUSETTS HISTORICAL SOCIETY

FIGURE 1. *The Massachusetts Medical Society in 1788.*

The Council met in the State House; the censors met in the Court House on Queen Street, the building on the right with the cupola.

"By what means would you resolve the inflammation?"

"By allaying the increased action of the vessels."

"How?"

"By astringents and sedatives."

"What kind?"

"Sometimes cold water is used, or saturnine applications."

"Suppose you could not resolve it?"

"If after endeavoring all in my power to resolve the tumor I should find it could not be done, I would bring it to suppurate."

"To mature, yes," said Dr. Gardner. "Well, by what means?"

"By emollient cataplasms."

"Pleurisy is known by a pain in the side, tightness over the chest, a cough, a fever."

"What are remedies to be used?"

"The chief remedy is blood letting."

"How soon would you bleed a second time?"

"If the pain of the side was great and respiration greatly obstructed, I would repeat the bleeding in a few hours."

Dr. Rand interrupted by asking how much blood a man could afford to lose. I replied, "I think I have seen an author who says we may take away as much as three or four pounds."

"Did you ever read Sydenham?" asked Dr. Rand.

"No," I answered.

"You ought to," replied Dr. Rand. "He says about forty-two ounces." But the other examiners all then said much more was frequently taken. After this interruption, Dr. Gardner continued, "What else would you do?"

"I would blister the side and if the patient would bear no more bleeding and symptoms continued violent, I would cup and scarify the side and draw some blood that way."

"Would you do anything else?"

"I would use demulcents for the cough."

"What demulcents?"

"Flaxseed tea and such things," I answered. "I would also use diluents and nauseating doses to determine to the surface and relieve the extreme vessels. I would keep the body open and soluble."

Dr. Rand now interrupted by asking, "What is a bilious fever?" I was considering what description it would bear when he said it was a typhus he meant, which rendered the matter more obscure. I told him a bilious fever arose from acrid bile being absorbed. Dr. Rand asked, "What is the predisponent cause?" I could not tell; for I could not reconcile bilious fever and typhus being the same thing. Dr. Rand asked me if the season was not the predisponent cause and what season typhus happened in. I said, "Toward the close of summer." "Do you not mean in the autumn?" then said he. I told him I supposed heat was an occasional cause.

"No," said he. "What is the cure?"

"Evacuants, diluents and refrigerants," I replied.

Dr. Gardner asked what I meant by diluents. I replied, "Water and teas that contain a great deal of water."

It was now Dr. Lloyd's turn to question me in Surgery. Said he, "You have seen amputations. Describe one, for instance below the knee."

I answered, "I would place the patient on a table of a convenient height."

"Stop!" said he. "Where are your dressings?" I told him I thought it unnecessary at this time to describe such minutiae. He went into a pathetic encomium on the wisdom and ingenuity of a surgeon who should have the foresight and address to prepare every article that should be necessary. So I enumerated double-headed roller, needles, tenaculum, great knife, cutting saw and retractor.

"Where is your lint?" asked Dr. Lloyd, "and would you not have something of a pledget and a cross bandage?" I enumerated these various articles and was about to describe how I would place them all in a convenient dish. Here I was so in-

terrupted by proposals, repetitions and so many questions that I was confounded and held my tongue.

Dr. Gardner said, "Take time, my dear, we don't mean to catch you."

At last I got the patient on the table again.

"How high a table?" asked Dr. Lloyd.

I answered, "One of convenient height—about two and a half feet high."

I believe that he said three feet high, and then turning to the others said, "That is the proper height."

At length I had a chance to continue. "I would secure him by two assistants, and place the tourniquet on the artery."

"Where?"

"Toward the groin," I said, "where I could feel the vessel beat. I would have an assistant to command the tourniquet, one to draw up the skin, and another to support the leg. I would then take the great knife and desire the assistant to retract the skin a little, making the incision a hand's breadth below the knee."

Dr. Gardner asked me to point where, and I pointed to the proper place. Dr. Rand said, "Of course you chose this point to avoid the tendon of the patella," and I answered, "Yes." I then went on, "After I had made the incision through the cellular membrane I would beg the assistant to retract the skin and cellular substance a little, and would make the second incision as high as possible and down to the bone."

"Straight?"

"Yes." I was going to apply the retractor when Dr. Rand asked, "Where is your catlin? If there is a portion of muscle undivided between the bones the catlin must be used." This interruption made me forget the retractor and they said nothing about it, so I continued. "I would then take the saw and saw through both bones and take the limb away. After clearing away the blood I would ask the assistant to loosen the tourniquet; whatever arteries I could find I would draw out with the tenaculum and have an assistant to tie them, repeatedly requesting the person who commanded the tourniquet to loosen it that I might discover the arteries."

Dr. Rand interjected another question. "Would you not wipe away any clotted blood with a sponge?"

"Yes."

"What would you do next?"

"I should draw the lips of the wound as near together as possible over the bones and secure them by ligatures."

'By needles do you mean?' asked Dr Rand

Undesignedly I said, 'Yes,' and immediately he said he should not think of it unless the lips of the wound were flabby. While he was saying this I saw the error I was led into and interrupted him 'I would secure them with sticking plaster,' I said, 'and then I would apply a pledget of some emollient ointment.'

'No lint?'

'No,' I answered. They then consulted together and concluded that lint was necessary. At length I continued 'I would place on the cross bandage and apply the roller.'

'How long should the bandage be?' asked Dr Lloyd

'Four yards would bring it round the thigh and secure it'

'Would you not secure it to something passed around the waist?'

'Yes. I would then get the patient to bed'

Dr Gardner asked me what to do afterwards. I said I would bleed if the pulse was hard and full. Dr Rand asked what should be done if the patient was irritable. I said 'If the pulse was low and the patient exhausted, I would give him bark and wine.'

Their frequent complaint of want of time and my expectation of being asked many more questions induced me to answer much quicker than prudence otherwise directed. But I recollect no other questions in surgery and I think I am able positively to say there was no other of any sort. Drs Rand and Gardner seemed by their motion to be done.

Dr Lloyd now drew out of his pocket a paper and said he had some more questions to ask me.

'What are the dimensions of the pelvis?'

I replied, 'Shall I mention bones first?'

'No, it is no matter'

The shortest diameter of the pelvis, from the base of the sacrum to the pubes, is about four inches and a half. From one ilia to the other, or from one side to the other side of the brim, five and a half inches.

Dr Lloyd said from side to side it was called, and Dr Rand asked if I meant from the spines to the ilia. I replied I meant the brim of the true pelvis.

'How is labor brought on?'

'About the ninth month, from the largeness and strength of the child, the uterus is excited to contraction, the abdominal muscles are brought into action by sympathy and thus are the throes of the woman produced.'

'How are labors divided?'

'Into natural and preternatural labors.'

'What is to be done in a natural labor?'

'We must do nothing but wait till nature expels the child.'

'Would you not set by the woman?'

'Yes, Sir,' I answered, 'and feel now and then if the child be in the right position.'

Dr Lloyd warned me that if I did not, I would soon lose all my business. Then he entered into another descant on the prudence of preparatory measures. I said I thought he only wanted me to give the fundamental principles. Dr Rand interrupted by saying 'Would you not support the perineum?'

'Yes,' I explained. 'What I meant by doing nothing is that we should use no violence.'

'You would receive the child, I suppose?'

'After the child was born I would tie the funis at about three fingers breadth from the navel, and cut it at nearly the same distance from the ligature. I would twist the navel string round the fingers of my left hand and introducing my right would take hold of the cord higher up. When the pains of the mother came on, I would pull down by the funis gradually at first in the direction of the coccyx, and moving it backwards and forwards would at last disengage the placenta.'

'Suppose the placenta will not come?'

'It is customary to desire the patient to blow in the fist, to cough and the like.'

'Suppose too there is a flooding?'

'I would extract the placenta as soon as possible, especially if the woman show any signs of deliquium.'

'Suppose the placenta still would not come?'

'I would introduce my hand into the womb and endeavor to separate it.'

Now Dr Rand said, 'Suppose the woman faint and the flooding stopped, would you now think of extracting the placenta?' I am not certain how I answered this question.

'What is a laborious labor?' continued Dr. Lloyd

A laborious labor is when the child cannot be delivered without the use of instruments.'

Dr Rand said he believed I was mistaken. A laborious labor was when the head was large and the pelvis small or rigid. I told him that Orme called such labor a lingering labor, but when recourse was to be had to instruments he called the labor laborious.

'Give us an instance of preternatural labor, how to deliver a breech or, let us say, an arm presentation.'

'When the arm presents and the os uteri is sufficiently dilated, break the membrane and push

up the body. at the same time endeavor to get the feet; having got them extract by the feet."

"How is it in the case of twins?" asked Dr. Lloyd.

"The twin case is merely like the others."

"When one child is born what do you do?"

"Suppose the placenta adheres to the os uteri when labor comes on, or when by introducing your finger in the os uteri you can feel nothing but the placenta, what is to be done?" asked Dr. Lloyd.

"I would separate the adhesion and deliver the child as soon as possible."

A leading surgeon and obstetrician of Boston and a conscientious censor of the Massachusetts Medical Society.

"Wait for the descent of the other."

"If," said Dr. Rand, "after the first child be born and you have cut the navel string, and after the first gush of blood is over bleeding should continue, what would you think of?"

"I should suspect another child and would secure the funis and wait for the other child."

"Should you not extract the placenta?"

"No," I answered.

"Suppose the other should not readily come?"

"After some time I would feel for it and extract it."

"Suppose during this time the woman floods or bleeds to death?"

"I know of no way to prevent it."

"Did you ever read of such a case?" said Dr. Rand.

"I do not recollect. Dr. Warren told me once of having such a case."

Dr. Rand once again interjected his ideas. He asked me if I had ever examined a placenta. If I had, he said, I would know that it is divided into lobes and that these were connected together by cellular membrane. "In this last case, these lobes

should be divided by the finger and the cellular membrane should be separated: this may be done without effusion of blood." I asked the doctors if cases of this character were not generally fatal. They all answered, "By no means."

"How do you distinguish pregnancy from amenorrhoea?" finally inquired Dr. Lloyd. Before I

The question subsided and I was dismissed. After this ordeal, I realized that all medical knowledge was not shut up in the brains of my professors.

* * *

John Fleet was a member of the first class to graduate in medicine from the Harvard Medical

Course of Examination.

Dr. Rand. Describe the process of deglutition? The food is first taken into the mouth, divided by the teeth—pushed backwards by the muscles of the throat. Is there any thing to prevent it from passing into the trachea? The glottis is immediately added; the epiglottis, I mean—that covers the glottis. What is the epiglottis? a cartilaginous substance. Proceed in the process? The food is pushed into the oesophagus & passes down to the stomach; is there mixed with the gastric juice & operated upon by the stomach; if a vegetable food be used a fermentation takes place. What is the upper orifice of the stomach called? Cardia. What the other? Pylorus. It is next introduced into the duodenum, there it mixes with the pancreatic juice & bile. What conveys the bile into the duodenum? Ductus communis, & duodenus. Does the hepatic duct enter the duodenum? Ductus communis & duodenus. Almost always. Proceed with the food? The food being mixed with the bile & pancreatic juice & what use is the bile? It is indigestible, he repeated the question. It appears to form chyle I answered. Go on? It goes into the small intestines, the chyle is absorbed by the lacteals. What are the lacteals? Vessels that convey chyle to the receptaculum chylei (Dr. Gardner asked where does it lie? I do not exactly remember upon which vertebra of the loins) What does the chyle pass through in going to the receptaculum chylei? Muc.

"These notes were taken the evening and day following my examination, being advised so to do before examination as a matter of satisfaction." Their accuracy was solemnly attested to before J. Brooks, justice of the peace.

had a chance to reply, Dr. Gardner got up and said with some exclamation, "Don't ask him that question for I never knew myself!"

School and was the first assistant appointed in the Department of Medicine. He was the first librarian of the Boston Medical Library.

He wrote his account of his examination by the censors of the Massachusetts Medical Society in the evening following the afternoon on which it was given. The manuscript was found recently in the Massachusetts Historical Society and is now printed through the courtesy of Mr. Allyn B. Forbes. It has been edited slightly by Dr. Reginald Fitz.

The censors did not consider Dr. Fleet's per-

formance on the occasion passable. He was made to undergo re-examination a few weeks later, when he passed with flying colors.

The questions asked and the answers given serve not only as an example of an early general medical examination but also reflect fairly representative New England medical opinion in that era.

DIAPHRAGMATIC HERNIA PRESENTING THE CLINICAL PICTURE OF ACUTE COR PULMONALE*

Report of a Case

SYLVESTER MCGINN, M.D.,† AND LOUIS M. SPEAR, M.D.‡

BOSTON

THE acute cor pulmonale was originally described¹ as a sudden distention of the chambers of the right heart as a result of an obstruction to the pulmonary circulation by a pulmonary embolus. A case of acute cor pulmonale has recently been observed, however, in which interference with the pulmonary circulation was caused by a diaphragmatic hernia. The case is interesting because of the age of the patient, because it was one of the first cases of diaphragmatic hernia to be recognized by roentgenogram, and because of the similarity of some of the symptoms to those of coronary disease and diaphragmatic hernia. The recognition of these clinical conditions and the establishment of the correct diagnosis may completely alter the prognosis and may change the therapy to include lifesaving surgical measures.

Cyanosis always suggests the possibility of a cardiovascular abnormality, and the commonest cause of its acute form is pulmonary embolism followed by an acute cor pulmonale. Brewster² and Stoll³ have reported 2 cases of diaphragmatic hernia, however, in which the outstanding features were cyanosis and dyspnea. Not infrequently, symptoms caused by diaphragmatic hernia have been erroneously attributed to cardiac disease. Healey⁴ noted that substernal discomfort, sometimes with left shoulder pain, and regurgitation of food when the patient was in the supine position were the commonest complaints of 53 of the earliest reported cases of diaphragmatic hernia. Stobie⁵ has reported that in addition to gastrointestinal symptoms, patients with this condition may have

mid-epigastric distress, with pain referred to the shoulder and down the arm, palpitation, tachycardia and dyspnea. Roch⁶ has discussed a case of angina pectoris that was falsely diagnosed because of symptoms associated with a diaphragmatic hernia. Electrocardiographic changes depending on the gaseous distention of a diaphragmatic hernia have been observed by Kalk and Koelsch⁷ who believe that there are variations in the coronary blood flow due to vagal irritation caused by the hernia.

CASE REPORT

An 81-year-old woman entered the hospital for the third time on March 13, 1940. She had been quite well until 1919, when she was first troubled with attacks of difficult breathing and pain in the left precordium. It was thought that she did not have angina pectoris. There had been one severe attack marked by dyspnea and cyanosis that was similar to the one described in the present illness. Physical examination at that time was negative, except that the blood pressure was 180/110, and the heart was enlarged to the left.

In 1925, a secondary anemia was found, and this condition persisted throughout the rest of her life. Roentgenograms made in 1930 showed a diaphragmatic hernia (Fig. 1). A fall in 1931 resulted in a fracture of the tenth dorsal vertebra, the treatment of which was complicated by the inability of the patient to wear a cast or to be maintained in the recumbent position. A dorsal kyphosis became increasingly noticeable after this accident. In October, 1939, she was again examined for a questionable angina pectoris, and an electrocardiogram was taken (Fig. 2). She had been suffering from mid-epigastric, low substernal distress and indigestion after meals. It was concluded that these symptoms were caused by the herniation of the stomach and were not of cardiac origin.

One week before admission, the patient became overtired and remained in bed for 3 days. The liver edge was palpated below the costal border, but except for fatigue, she seemed in her usual health. On the day of admission, she was drowsy, although she could be aroused.

*From the Robert Breck Brigham Hospital.

†Instructor, Courses for Graduates, Harvard Medical School; assistant in medicine, Massachusetts General Hospital; cardiologist, Robert Breck Brigham Hospital.

‡Chief of the Medical Service, Robert Breck Brigham Hospital.

Respirations were rapid and shallow, and the lips and fingernails were very cyanotic. There was no pain at any time.

Physical examination showed an elderly woman with increased shallow respirations. Cyanosis of the nails, lips, ears and cheeks was marked, and there was marked blueness of the skin. The neck veins were greatly distended. The pulmonic second sound was accentuated and was much louder than the aortic second sound. Neither of these findings was present 2 days before admission. The heart was enlarged in the region of the

On the 4th day after admission, the patient was unable to take nourishment and became much weaker. The temperature rose to 103.2°F, and the pulse rate was increased to 130 at intervals throughout the day. Bronchial breathing was heard over the left lung posteriorly. The patient expired on the 5th day after admission.

Autopsy. A post mortem examination was made by Dr J. B. Hazard. Kyphosis of the thoracic spine was present and dependent lividity was marked. About 200 cc of amber fluid was found in each pleural cavity. The entire stomach, as far as the pylorus, projected into the

FIGURE 1 X-Ray Films Taken on June 9 1930

A—Herniation of the stomach through the diaphragm (film taken before the barium meal)

B—Barium filled stomach showing the cardiac end protruding through the diaphragm of the esophageal hiatus and extending into the right thorax behind the shadow of the heart

left ventricle, the mid-clavicular line equalling 8 cm. the left border of dullness and maximal apex beat was in the fifth interspace, 10.5 cm from the midsternum. The heart sounds were of good quality without significant murmurs and were regular except for extrasystoles; the rate was 78. The blood pressure was 155/90. A few fine rales were heard at the left lung base. The lower edge was palpated three fingerbreadths below the costal margin. Varicose veins and slight pitting edema were present in both legs.

The patient's condition improved slightly when she was placed in an oxygen tent. It was observed that she was very cyanotic while the oxygen tanks were being changed. It was believed that the liver was not so enlarged as it had been on admission, but palpation was difficult owing to abdominal distention, which markedly intensified the cyanosis.

A roentgenogram of the chest was taken with a portable machine and an electrocardiogram was made; the interpretations accompany the illustrations (Figs 3 and 4). The nonprotein nitrogen was 45 mg per 100 cc, and the white cell count 8650.

right thorax through an opening 6 cm in diameter in the diaphragm at the esophageal hiatus. It was covered by a thin fibrous layer continuous with the diaphragmatic leaves. The left lung weighed 380 gm, the right 570, and both the right and left lower lobes were flabby, airless and, on section, purplish red. The upper lobes were grayish, hypercrepitant and easily compressed. The primary bronchi were purplish gray, and their mucosa purplish red. The branches of the pulmonary artery were wide, but the walls were of average thickness, with only occasional small yellowish plaques. No evidence of ante mortem clot was found.

The heart weighed 500 gm and the right auricle and ventricle were dilated. The right ventricular wall measured 0.8 cm in thickness and the left varied from 1.5 to 1.8 cm, both ventricles being enlarged. The foramen ovale was not patent, and the valves were normal. The coronary arteries were patent throughout although there was some diminution in the size of the lumen of the left descending branch secondary to thickening of the intima and calcification.

The liver and spleen appeared to be enlarged, with

approximate weights of 1800 and 300 gm. respectively, the organs not being removed. The stomach presented a purplish-gray mucosa as far as the pylorus, where it assumed a grayish tint. No evidence of necrosis of the gastric wall was found. The kidneys appeared grossly to be of average size, with a purplish-red, slightly granular surface.

Microscopic examination of the sections from the low-

marked right ventricular hypertrophy and dilatation (cor pulmonale), left ventricular hypertrophy, pulmonary atelectasis (right and left lower lobes), pulmonary emphysema, diaphragmatic hernia of stomach into the right chest, passive hyperemia of the stomach, passive hyperemia of spleen and liver, and slight bilateral hydrothorax.

For many years the patient had a diaphragmatic hernia, apparently of congenital origin. It is of interest that despite this deformity she lived until her eighty-second year in average good health, but that the condition finally caused her death. A secondary anemia had been present for a long time, and is best explained as due to slow bleeding from hyperemic and congested vessels in the gastric mucosa, as the microscopic sections from the stomach wall suggested. This indicates that there was an interference in the blood supply to the stomach, and that there was an impairment to the venous return flow by constriction at the point of the passage of the stomach through the diaphragm. The association of a secondary anemia and a diaphragmatic hernia has been pointed out by Bock, Dulin and Brooke.⁸

The patient had a mild hypertension, which undoubtedly caused hypertrophy of the left ventricle and contributed to the cardiac enlargement. The right ventricular wall measured 0.8 cm. in thickness; this hypertrophy indicated a chronic cor pulmonale. Right ventricular strain in this case resulted from an increase in pulmonary pressure due to emphysema, which was compensatory to either or both the kyphosis and the fact that the herniated stomach was occupying space in the thoracic cavity that should have been available to the lungs. In addition to the chronic cor pulmonale, marked dilatation of the right auricle and ventricle were observed and confirmed the clinical impression of an acute cor pulmonale. The increase in the venous pressure was shown by the distention of the neck veins, and the increase in pulmonary pressure by the accentuation of the pulmonary second sound. Judging from the roentgenograms, about one third of the stomach was usually present in the chest, and apparently the entire stomach suddenly herniated through the esophageal hiatus into the right thoracic cavity. The lower lobe of the right lung and, to a lesser extent, that of the left lung were compressed and became atelectatic. This caused an acute rise in pulmonary arterial pressure, and the right heart, which was already weakened by chronic strain, became dilated and failed. Evidence of the amount of pressure exerted by the stomach on the lungs can be appreciated when it is considered that the liver was displaced downward three fingerbreadths below the costal margin. The liver edge was palpated at varying points

FIGURE 2. Electrocardiogram Taken on October 25, 1939.

There are normal rhythm, a rate of 70 and low T waves in all leads. The deep S wave in Lead 1 indicates a tendency to but not definite right-axis deviation. In Lead 4 the R wave is present, and there is a prominent U wave.

er lobes of the lungs revealed extensive hemorrhage into the alveoli; the alveolar walls were closely approximated. The connective tissue contained an infiltration of lymphocytes. Sections from the upper lobes showed distended alveoli with thin walls. Sections from the stomach wall showed the vessels to be engorged with blood.

Clinical diagnoses: Acute dilatation of the right side of the heart, probably due to a pulmonary embolus, diaphragmatic hernia, hypertensive heart disease and arteriosclerosis.

Anatomical diagnoses: Kyphosis of the thoracic spine,

below the ribs, depending in all probability on the amount of air in the stomach and not on passive congestion, as we had thought before the post-mortem examination. The latter examination likewise failed to demonstrate emboli in the pulmonary arteries, which we had believed responsible for the condition, even though we were fully aware that there was also a diaphragmatic hernia. The outstanding clinical signs of cyanosis and dyspnea can be readily explained by the acute cor pul-

nite right-axis deviation. The T waves in Leads 1, 2 and 3 were low. It was believed that the tracing showed no evidence of significant coronary disease. The electrocardiogram made on March 14, 1940, the day after admission to the hospital and four days before death, differed considerably from the previous tracing. Marked right-axis deviation was present, and although the T waves in Lead 1 were still low, those in Leads 2 and 3 showed late and deep inversion. R waves were

FIGURE 3. *Electrocardiogram Taken on March 14, 1940.*

There are normal rhythm, a rate of 80 and low T waves in Lead 1 (as before), but also late and deep inversion of the T waves in Leads 2 and 3 and very deep S waves in Lead 1, indicating marked right-axis deviation. In Lead 4, the R wave is present and there is high origin of the T wave. There are prominent U waves in Leads 1 and 4.

monale. It is likely that the attack of cyanosis and dyspnea in 1919 was similar to the final illness, except that the hernia reduced itself at that time.

Roentgenograms made in 1930, which were the earliest we could locate, showed part of the stomach herniating through the diaphragm into the right chest. The picture made on the day after admission, four days before death, revealed that a larger portion, if not the entire stomach, had herniated through the esophageal hiatus and had replaced the usual dense shadow of the liver. The lung fields failed to show definite evidence of infarction, and the mottled dullness above the outline of the stomach was due to atelectasis. The heart shadow was enlarged at both examinations.

The electrocardiogram made on October 25, 1939, showed a prominent S wave in Lead 1, but no defi-

present in Lead 4, but there was high origin of the T waves. It was concluded from this electrocardiogram, together with the clinical history and the previous tracing, that an acute cor pulmonale was present.

The substernal discomfort created by a diaphragmatic hernia may readily lead to the diagnosis of angina pectoris, but the symptoms of the former condition are invariably provoked by eating and by the recumbent position rather than by exertion. The clinical picture of the present case was indistinguishable from that of an acute cor pulmonale, which we had always previously thought to be the result of an embolus in the pulmonary circulation. A roentgenogram can immediately produce evidence to differentiate these three clinical conditions; it is essential that they be diag-

nosed correctly, for the prognosis is serious in two of them, whereas patients with diaphragmatic hernias may live comfortably for many years.

If the condition illustrated by this case should be encountered again in a younger person with

FIGURE 4. X-Ray Film Taken on March 14, 1940.

The greater part of the stomach occupies the lower right thorax and replaces the usual density of the liver. A mottled area is seen above the stomach shadow. The heart is enlarged and obscures the left lung base.

a more favorable operative outlook, surgical reduction and repair of the hernia would be seriously considered. Surgical discussions of this type of hernia are numerous, among them being those of Truesdale⁹ and Sloan.¹⁰ In 210 cases of dia-

phragmatic hernia surgically treated and reported by Harrington,¹¹ 195 patients were relieved of symptoms, 6 hiatus hernias recurred and 9 patients died. These data indicate definite improvement in the operative treatment of diaphragmatic hernias, chronic, traumatic or incarcerated, and justify surgical intervention, which in cases similar to the one reported may be a lifesaving procedure.

SUMMARY

A case of diaphragmatic hernia in an eighty-one-year-old woman is reported, including the post-mortem findings. The clinical symptoms were those of an acute cor pulmonale with marked cyanosis, dyspnea and electrocardiographic abnormalities. Compression of the lungs by an increase in the amount of stomach herniating through the diaphragm caused an acute strain on the right side of the heart. The differential diagnosis of coronary disease and diaphragmatic hernia, with possible surgical repair of the latter, is discussed.

THE MOUTH IN HYPERPARATHYROIDISM

MOSES S. STROCK, DMD†

BOSTON

IT HAS long been known that careful clinical and radiographic examinations of the mouth will occasionally reveal the symptoms of systemic disease. This observation has been strikingly brought out in hyperparathyroidism. This article describes a summary of the dental findings and illustrates each oral symptom of a series of 45 cases of hyperparathyroidism. The normal oral findings should lead to a more detailed examination, and not infrequently to the recognition of hyperparathyroidism.

Knowledge of the parathyroid glands has only recently evolved. It is difficult to believe that the glands were unknown until 1880, and that tumors of the parathyroid were first discovered in 1915. It is, therefore, no wonder that the dental findings are entirely new to most observers despite Erdheim's early observations on the effect of these glands on the teeth.

The clinical syndrome of osteitis fibrosa cystica has been known for a long time, but no great interest was excited until Mandl¹ in 1925 discovered, through the removal of an enlarged parathyroid gland, what caused the disease. Castleman and Mallory,² in 1934, stated that the number of cases reported at that time had reached 100. Since no investigator had reported more than 6 cases, these authors considered that the series of Albright and his co-workers,³ which numbered 20, warranted a summary on the pathology of parathyroid disease. The Massachusetts General Hospital series has, since then, grown to 51 cases, and this report covers 45 patients.

This group of cases has been studied from the dental point of view, and the dental findings have been presented elsewhere.⁴⁻⁶ The chief findings include visible or palpable tumors of the jaw, malocclusion or distortion of the normal arrangement of the teeth (motility); cystlike cavities of the jaws, diminished dental caries; osteoporosis, closely meshed trabeculae, and absence of the lamina dura.

The case history of the famous Captain Martell serves to point out the difficulties accompanying the correct diagnosis, and the post mortem findings refute the observations of others⁷ that pyorrhea

or looseness of the teeth occurs with the decalcification of hyperparathyroidism. This patient was known to have had the disease for thirteen years. He had shrunk from a tall sea captain to a bent and shortened cripple. The serum calcium had ranged from 13.1 to 16.5 mg per 100 cc, and the phosphorus from 1.4 to 3.2 mg. It required seven operations, the last an anterior mediastinotomy,⁸ to locate the parathyroid tumor. The calcium and phosphorus excretions had been distinct

FIGURE 1 Malocclusion or Jaw Distortion in Advanced Hyperparathyroidism

Note the protrusion of the lower teeth outside the upper arch. The distance was 1.5 cm in the right lateral incisor region in this case. Because of extreme prognathism the lower lip was hardly adequate to cover the new position of the mandible. The force of the tongue had distorted the mandibular arch. Despite the softness of the bone, the teeth were dislodged with difficulty at autopsy, and there was no evidence of periodontal disease. This intelligent patient said that seven years earlier, when his disease was known to have begun, his teeth were in normal occlusion.

ly elevated for a long period, and the entire skeleton was markedly demineralized.

When the patient's mouth was examined, the following dental symptoms were found, which were reported by Albright, Aub and Buier.⁴ The jaws were in marked malocclusion (Fig 1). The lower jaw was prognathous to such an extent that the entire mandibular dentition was in mesial occlu-

The author is oral surgeon, Harvard Dental School; oral surgeon, Peter Bent Brigham Hospital, and Massachusetts General Hospital.

sion. Several visible masses distorted the normal contour of the alveolar process. By radiogram numerous punched-out areas resembling cysts could be seen (Fig. 2). The entire mandible was osteoporotic, and in sharp contrast to well-calcified teeth. The trabeculation of the mandible and maxillas was closely meshed and similar to ground glass in appearance. The lamina dura was ab-

pleted of calcium and phosphorus that it was possible to mold the shape of the jaw by the pressure of one's fingers, yet there was no apparent lack of calcium in the teeth, clinically or by radiogram. This was more apparent at autopsy. The fingers holding the upper jaw could easily mold the maxillas to any shape. The teeth returned to their earlier position on release of pres-

FIGURE 2. *Changes Due to Hyperparathyroidism.*

Note the lack of lamina dura, the diminished trabeculation, the remarkable contrast of the teeth against the bone, the lack of caries and the cystlike cavities.

sent from almost all the teeth. Despite this, radiographic examination showed only one or two obvious cavities. The history revealed that in the patient's numerous hospital stays for thirteen years his dental attention had been limited to one or two temporary fillings, and that his occlusion had been normal fifteen years earlier.

Here was a patient whose bones had been so de-

sure. They were not loose, and a specimen tooth was extracted only with considerable effort.

Bauer⁷ summarized the alterations in the calcium and phosphorus metabolism and said that they could be accompanied by any or all the following signs and symptoms: polydipsia, polyuria, weakness and loss of strength, constipation, loss of appetite, loss of weight, indefinite muscle and

joint aches and pains,—commonly diagnosed as "rheumatism," arthritis or neuritis,—bone tenderness, frequent fractures,—often following slight trauma,—decreased excitability of the nerves, skeletal shortening, kyphosis, bone tumors,—fre-

roidism. This also applies to certain types of bony growths, which will be spoken of below.

Malocclusion

In several cases, malocclusion or jaw distortion was one of the earliest presenting symptoms (Figs. 1 and 5). Prognathism of the mandible, which develops suddenly and without any apparent cause, especially in adults, should be regarded with suspicion. If such prognathism is associated with separation of the teeth, it may be an important clue to the early recognition of the disease. Likewise, the sudden separation of the teeth in any locality of the maxillas or mandible is to be regarded with suspicion, since it may be evidence of a tumor that by its proliferation has mechanically caused a separation of the teeth. Certainly such conditions warrant thorough x-ray study. Figure 1 shows the protrusion of the lower jaw in a patient who previous to the onset of the ailment had normal occlusion.

Cysts

Perhaps the most striking change in the jaw bone is the occurrence of cystlike cavities visible

FIGURE 3. Visible and Palpable Tumor.

This growth was biopsied and proved to be a giant-cell tumor. Note the cyanotic enlargement over the right lateral incisor and the partial obliteration of the labial fold. The patient was a young girl.

quently diagnosed as epulis of the jaw or giant-cell tumor in other bones,—kidney or ureteral stones—usually bilateral—and, frequently, anemia with leukopenia. The characteristic x-ray findings were generalized decalcification, bone tumors, multiple bone cysts and fish-type vertebral bodies. However, the earliest presenting symptom may be in the mouth, as a considerable number of the cases reported in the present paper indicate.

Tumors

Of the 45 cases, about half showed tumors of the jaw (Figs. 3 and 4); one presented large, smooth masses in both maxillary cuspid regions that were difficult to differentiate from the swellings normally found prior to the eruption of the maxillary cuspid; several presented soft-tissue masses that might have been taken for ordinary benign giant-cell tumors.

In view of the similarity in histologic structure between the benign giant-cell tumors often found in the mouth and the giant-cell tumors found in osteitis fibrosa cystica, every case presenting a nonmalignant tumor of the soft tissue should be investigated for the possibility of hyperparathy-

FIGURE 4. Distortion of the Upper Right Maxilla Due to Hyperparathyroidism.

by x-ray (Figs. 2 and 6). These may be unilocular or multilocular and may or may not be associated with pulp disease. In advanced cases the entire mandible may be honeycombed by multiple cystic cavities. Cysts of unknown origin that seem to occur independent of apical disease should create in the observer a desire to know more about their etiology.

Caries

Paradoxical as it may first seem, caries is diminished (Figs. 2 and 7). This finding attracted great interest. Here was a disease in which calcium was being extracted from ev-

bone in the body and was being excreted. If it were possible to extract calcium from already formed teeth in this disease, one would expect

FIGURE 5. *Disturbance of the Occlusion and Movement of the Teeth.*

Note the space that has occurred between the upper central incisors and between the upper right lateral and central incisors. These were not present one year previously. No tumor is visible or demonstrable, but the general decalcification of the jaws has permitted the forces of mastication to move the teeth in the direction of least resistance.

widespread caries. Instead of this, one finds the opposite. This phenomenon, which is consistently observed, indicates that calcium cannot be withdrawn through the blood stream from already cal-

FIGURE 6. *Changes Due to Hyperparathyroidism.*

Note the mandible honeycombed by multiple cystlike cavities, which may resemble the cysts that result from periodontal disease.

cified dental tissues. This opinion has found general recognition in the literature.

Osteoporosis

In the x-ray films of patients with bony changes due to hyperparathyroidism, the teeth stand out so that they seem in contrast radiopaque, whereas the bone is radiolucent (Figs. 2 and 7). In other words, in osteoporosis of the supporting bone,

when calcium has been withdrawn, the teeth remain at their usual radiopaque level.

Bone Trabeculae

What bone remains has very finely meshed trabeculae, which can hardly be seen, and appears in a symmetrical pattern of lacelike delicacy, often described by radiologists as resembling ground glass (Figs. 2 and 7).

Lamina Dura

The most striking finding is the one for which every dentist should be on the watch, since it must suggest hyperparathyroidism although it is also seen in diseases such as osteomalacia.¹⁰ It is the absence, or partial loss, of the lamina dura—the thin layer of compact bone that abuts the periodontal membrane (Figs. 2 and 7). This structure

FIGURE 7. *Changes Due to Hyperparathyroidism.*

In the upper film, note the lack of lamina dura, the ground-glass appearance of the bone (closely meshed trabeculae) and the well-formed teeth, compared in the lower film with a normal lamina dura and normal trabeculation.

has been called the periodontal lamella, the lamina dura and the linea alba. In the x-ray films, the normal image of the lamina dura is a fine, even white line less than 1.0 mm. wide, with a slight thickening at the cemento-enamel junction on each side. It is never any wider except in early life or because of disease. The lamina dura is perhaps the most delicate layer of compact bone in the body, and it is the first bony barrier that infection from caries in a tooth meets in its effort to extend itself into the tissues of the body.

The lamina dura may be entirely absent, or it may be deficient in only a few localized spots in osteitis fibrosa cystica. In the less marked cases it may be merely extremely thin.

SUMMARY AND CONCLUSIONS

The frequency with which oral symptoms appear in hyperparathyroidism suggests that manifestations about the teeth are of value in recognition of the disease.

The dental symptoms are visible or palpable tumors of the jaw, malocclusion or distortion of the normal arrangement of the teeth (motility), cyst-like cavities of the jaws, diminished dental caries, osteoporosis, closely meshed trabeculae and absence of the lamina dura.

The fact that, even in extreme cases of demineralization in hyperparathyroidism, caries does not increase is convincing evidence that the resorption of calcium and phosphorus from mature teeth is impossible by way of the blood stream.

Disorders of the parathyroid gland should be

further studied to throw light on the etiology of dental diseases.¹¹

MEDICAL PROGRESS

PATHOLOGY

TRACY B MALLORY, M.D.*

BOSTON

THE experimental production of cirrhosis of the liver and its relation to the disease in man was thoroughly reviewed by Moon¹ in 1934. A brief summary will serve as a background for the interesting developments in the intervening years. Agreement was quickly reached by all experimenters that a biliary type of cirrhosis essentially identical with the human lesion could be produced by ligation of the common bile duct. Cirrhosis of the portal or Laennec type was first produced by Wegner² with phosphorus in 1872. In subsequent years, success was claimed for many other methods, all dependent on the use of one or another hepatotoxic agent. The methods can be roughly divided into two categories: the prolonged administration of minute, individually nontoxic doses of agents such as phosphorus,² arsenic,^{3,4} lead,^{5,6} copper,⁷ manganese,^{8,9} silica¹⁰ and tar¹¹; and the repeated use of toxic but nonlethal doses of powerful organic liver poisons, particularly halogen compounds such as chloroform^{12,13} and carbon tetrachloride.^{14,15} Opie¹⁶ added another factor by combining toxic doses of chloroform with the injection of colon bacilli intravenously, but it is im-

probable that the experimental production of cirrhosis has ever been accomplished by the use of infectious agents alone.

The cirrhoses produced resembled in varying degrees atrophic cirrhosis as it is seen in man. Using copper, Mallory, Parker and Nye⁷ produced a cirrhosis with pigmentation reminiscent of hemochromatosis. Phosphorus and lead administration were shown by Mallory¹⁷ to result in cirrhosis, with hyaline degeneration of the liver cells similar to that seen in alcoholic cirrhosis of man. Other characteristic features of the human lesion, such as extensive fatty vacuolization and reconstruction of the liver architecture, were not observed. The cirrhosis produced with carbon tetrachloride and related compounds exhibited, in the most successful experiments, pictures closely resembling the so called "toxic" or postatrophy cirrhosis of human beings. Throughout the long list of demonstrated effective agents, not one can be singled out that seems a probable cause of a significant proportion of cirrhosis in man. Most efforts to induce cirrhosis with the agent that clinical experience rates most important—ethyl alcohol—were flatly unsuccessful, and the few re-

*Assistant professor of pathology, Harvard Medical School; director, Department of Pathology and Bacteriology, Massachusetts General Hospital.

ported positive results were at best equivocal. After critical survey, Moon, in agreement with the opinion of the vast majority of pathologists, decided that no credible evidence of the experimental production of cirrhosis with alcohol existed.

That alcohol was not without effect on the liver could not, however, be denied. Bollman and Mann,¹⁶ like others before them, produced large fatty livers by prolonged administration of alcohol to dogs, but necrosis and fibrosis did not occur. Moreover, the administration of alcohol to dogs subsisting on a high-fat diet, which, it is well known, will of itself produce a fatty liver, markedly accelerated the rate of fat infiltration, but again no cirrhosis resulted. An adjuvant effect of alcohol in increasing the toxicity of various agents on the liver was reported by Fischler¹⁸ following the use of phosphorus, and by Lamson and Wing¹⁴ with carbon tetrachloride. Bollman and Mann¹⁵ have confirmed both experiments.

Despite the failure of so many experienced investigators to demonstrate the progression of a chronic fatty infiltration into a cirrhosis, numerous observations during the last two years indicate that this frequently occurs if the experiment is sufficiently prolonged. Allan, Bowie, McLeod and Robinson¹⁹ noted that in depancreatized dogs kept alive with insulin for long periods fatty livers regularly develop. Chaikoff, Connor and Biskind²⁰ found that in similar animals surviving for periods of two to four years the fat gradually disappeared from the liver, which grew progressively smaller and in many cases became definitely cirrhotic. The resulting cirrhosis closely resembled so-called "alcoholic cirrhosis" of man. The parallel to the not infrequent large fatty livers and the occasional development of cirrhosis in human diabetic patients was pointed out.

Pursuing this clue with vigor, Connor and Chaikoff have reported²¹ the development of cirrhosis in 4 of 16 dogs receiving a high-fat diet in addition to large doses of alcohol, and even in a number of dogs treated with a high-fat diet alone.²² It is interesting that in the latter the scarring was more diffuse and less similar to human portal cirrhosis than in the dogs that had received alcohol as well. Similarly, in rabbits, which were fed a low-carbohydrate, high-fat diet and given alcohol by stomach tube for weeks and months to the limits of tolerance, Connor²³ reports the appearance of cirrhosis in 7 of 20 animals surviving the regime for more than a few weeks. In many of the degenerating cells, coarse "hyaline" networks developed in the cytoplasm of the hepatic cells, corresponding to the picture regarded by Mallory as pathognomonic for alcoholic cirrhosis.

In human alcoholic patients Connor²⁴ has also been able at the autopsy table to trace all stages of progression from the large smooth fatty liver, which is the most constant anatomic finding in chronic alcoholism (Fahr,²⁵ LeCount and Singer²⁶), through a hypertrophic stage of cirrhosis to eventual atrophy, a progression fully confirmed in a similar study by Hall and Morgan.²⁷

Connor's success when so many others have failed can scarcely be attributed to persistence alone, and constitutes a challenge to further study and experiment. Connor himself argues for a direct metabolic effect of alcohol and suggests that it interferes with normal tissue oxidative mechanisms, as do many of the other hepatotoxic agents, such as phosphorus and carbon tetrachloride, and as certainly happens in uncontrolled diabetes. Direct evidence that ethyl alcohol exerts such an effect on the liver appears to have been furnished by Newman, Van Winkle, Kennedy and Morton.²⁸ Several other possibilities, however, are suggested by recent investigations.

Among the multitude of toxic effects attributed to alcohol in the past, recent investigation has proved one after another—peripheral neuritis²⁹ and chronic myocarditis,³⁰ for example—to be in fact manifestations of vitamin deficiency curable in many cases without deprivation of alcohol by the administration of vitamin concentrates. In this respect, it is interesting that Rich and Hamilton³¹ have been able to produce cirrhosis in rabbits with a diet deficient in vitamin B. The exact nature of the deficiency is still undetermined. Evidence points to a factor present in yeast other than vitamins B₁, B₂ and B₆ or nicotinic acid. In experiments carried from twenty-five to one hundred and thirteen days, the livers were smooth to finely granular, cut with increased resistance, and showed a diffuse cirrhosis, which was at first limited to the portal areas but later invaded the lobules. Fat was present in some specimens, absent in others. Necrotic liver cells were usually difficult to find. The cirrhosis evidently closely resembles and may actually prove to be indistinguishable from alcoholic cirrhosis in man.

Significantly different effects were obtained by György and Goldblatt,³² who used another experimental animal, the rat, with a similar deficiency of an unidentified radicle of the vitamin B complex. In contrast to the rabbits of Rich and Hamilton, the rats developed extensive focal necroses with precirrhotic changes resembling the picture of acute yellow atrophy in man. The addition of yeast extract regularly prevented this hepatic injury. Further evidence of an important protective factor in yeast are the reports by Von Glahn

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27241

PRESENTATION OF CASE

First Admission. A fifty-six-year-old woman entered the hospital complaining of recurrent attacks of severe crampy abdominal pain of approximately two years' duration. The pain tended to be on the right side of the abdomen, often radiated to the right flank and costovertebral angle, and lasted about two hours. This symptom was accompanied by urgency, frequency, burning and nocturia. X-ray examination showed a moderate dilatation of the right ureter without apparent cause, and kidney outlines and function tests were normal. Cystoscopic examination revealed an edematous right ureteral orifice, with surrounding cystitis cystica.

The patient returned five months later with the same complaints, and tubercle bacilli were found to be coming from the right kidney. A right nephrectomy was performed, and pathological study confirmed the diagnosis of tuberculosis. During hospitalization, a gastrointestinal series, barium enema and Graham test were negative.

Final Admission (four years later). In the interval the patient had felt perfectly well until two months before admission, when she began to suffer from attacks of heavy, sometimes crampy non-radiating pain in the right side of her abdomen. The pain was not too severe, although it sometimes precluded sleep; it was more intense after meals, but it was apparently not governed by the type of food eaten. The attacks occurred at intervals, although never separated by more than a week. There were accompanying anorexia and a weight loss of ten pounds. The patient denied urinary symptoms or change in bowel habits or the character of her stools.

The patient had had measles, scarlet fever, typhoid and pleurisy. Twenty years before admission, a panhysterectomy and appendectomy had been performed, and some time later a low back fusion for tuberculosis of the spine. X-ray films showed fusion of the vertebrae from the eleventh dorsal to the third lumbar.

The patient's mother had died at fifty-four of typhoid fever, her father at sixty-eight of a stroke. Several members of her mother's family had died of tuberculosis.

On examination the patient looked tired and showed evidence of recent weight loss, but she was not acutely ill. The heart and lungs were essentially normal, the blood pressure 105 systolic, 60 diastolic. The abdomen was slightly distended, and a moderately tender, hard, somewhat irregular mass could be felt both front and back filling the right side. It moved slightly with respiration, appeared to be below the liver area, and apparently was not connected with it. Extension of the thigh with the patient lying on her stomach produced no pain. A pelvic examination was negative.

The temperature was 99°F, the pulse 88, and the respirations 20.

The urine showed a + test for albumin, and the sediment contained ten white blood cells and an occasional red blood cell per high power field. The blood showed a red cell count of 4,500,000 with a hemoglobin of 11.3 gm (photoelectric-cell technique) and a white cell count of 15,200 with 93 per cent polymorphonuclears. The serum van den Bergh was normal, and the blood Hinton reaction negative. The stools were normal.

A plain x-ray film of the abdomen showed a large sharply defined mass in the right mid abdomen, which was distinct from the lower border of the liver and measured 12 cm in diameter. A moderate quantity of gas was present in the colon, but no dilated loops of intestine were seen.

A barium enema met an almost complete obstruction in the right side of the transverse colon. A large area of ulceration was present, with marked narrowing in the proximal end of the lesion, the area corresponding to the large palpable mass. The cecum was not dilated, and only a small quantity of gas was seen in the small bowel, without dilatation.

A Graham test was positive. There was a spinal fusion of the upper lumbar vertebrae; the bones of the pelvis and dorsal spine appeared normal.

X-ray study of the chest showed marked prominence of the heart shadow in the region of the left ventricle. The lung fields were clear.

An operation was performed on the eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR RICHARD H. SWEET. By the efforts of the surgeon, we can exclude several organs from the differential diagnosis.

The stools were normal. I cannot refrain from saying that that is a significant statement if true, because as I reflect on this case the differential diagnosis can be brought down to deciding between two or three very definite conditions, all of which usually cause bleeding into the stools. Yet

the record says the stools were normal. I hardly believe it, but we shall have to accept that statement in discussing the differential diagnosis.

DR. TRACY B. MALLORY: Only one stool examination was performed, and it was negative.

DR. SWEET: It is not very unusual to have what appears to be a complete obstruction by barium enema without clinical evidence of obstruction, such as distention. The barium enema may fail to pass even when intestinal contents may pass through from above. Is that not so, Dr. Holmes?

DR. GEORGE W. HOLMES: Yes, that is true.

DR. EDWARD F. BLAND: May I interpose here? I happen to have seen the patient. The record does not mention that a Miller-Abbott tube was passed shortly after.

DR. SWEET: That might have accounted for the absence of gas. May we see the x-ray films?

DR. HOLMES: The problem, of course, is to decide what the obstruction was due to. That there was obstruction is quite obvious. It is a well-known fact that when one gives a barium enema, as Dr. Sweet pointed out, the amount of obstruction always appears greater than it does when the barium is given by mouth. That is particularly true if the lesion in the bowel is fungating. It may form a cone so that the contents of the bowel pass through readily from above, but when the flow is started in the other direction there is a valve effect. I do not know how much one can rely on it, but it is of some value. It suggests that the growth is into the lumen of the bowel, not a simple ulceration. The Miller-Abbott tube is seen in position there. There is rather more gas in the bowel than the impression gained from the text would indicate. I do not believe that the bowel is definitely dilated, but there is more in the large bowel than one would expect. Here you see the evidence of obstruction, with the colon fairly well filled, and in this film, which was taken after evacuation, the normal mucosal pattern is shown throughout the large bowel, except for the area at the point of obstruction; I should say that there is absence of mucosa into a definite conelike effect, which we usually associate with carcinoma. Apparently, the lesion is single. The remainder of the bowel is extremely normal for tuberculosis. This film shows the meal given by mouth and does not give much added information. Here is a film taken of the chest, and it rules out metastasis to the lung and also evidence of active tuberculosis. As you know, ulcerative lesions in the colon are a little commoner in active tuberculosis, and we have no evidence of that here.

DR. SWEET: The differential diagnosis obviously can be narrowed down very promptly to deciding,

as Dr. Holmes has pointed out, between carcinoma and tuberculosis. The catch is that the patient had a lot of tuberculous infection elsewhere, but I presume that she had a carcinoma of the colon. The history would go with either lesion. She had attacks of pain, suggesting obstruction. She had intermittent attacks occurring at frequent intervals, I presume growing severer as time went on. The obstruction in itself might account for a certain amount of weight loss, anorexia and so forth, so that one need not postulate neoplastic disease to explain that symptom necessarily. Let us assume that this is carcinoma of the colon. One or two things about the case are unusual. A carcinoma in the right half of the colon is often associated with a severe degree of anemia. This patient had a red-cell count of 4,500,000, with only a fairly low hemoglobin. Oftentimes the degree of anemia that we see in carcinoma of the cecum and ascending colon is very severe. That, of course, would not exclude it. Again, the stools were normal. I do not believe that any carcinoma of the colon ever existed without microscopic evidence of blood in the stools. On the other hand, the history is very short and is quite consistent with carcinoma. The location in the bowel, that is, not down at the ileocecal region, but farther up in the region of the transverse colon, is a little more in favor of carcinoma than tuberculosis; also, as Dr. Holmes pointed out, in a tuberculous lesion of this type we are accustomed to seeing evidence of disease in the chest, and although that need not necessarily be the case, it seems to me that we should expect it.

On looking at the case from the standpoint of tuberculosis, there are many things in favor of that diagnosis: the facts that the patient has had active tuberculous disease in the spine and in the right kidney, and that she had a positive family history. The clinical history of the case, the intermittent obstruction and so forth in the presence of the palpable mass would go with such a diagnosis perfectly well. But, as I have said, there is absence of active pulmonary disease, and the history is rather short. I should expect also to find a certain amount of blood in the stools with any ulcerative lesion, whether tuberculosis or carcinoma. We might mention one or two things in passing. I thought about actinomycosis until I saw the x-ray film, but now I should exclude it. Usually in association with that we see fistulas, and there were none in this case. Such things as lymphoma might be spoken of. Lymphoma of the colon is not at all unusual. I do not know enough about the interpretation of the x-ray films to know whether it has a characteristic appearance or not.

DR. HOLMES: I do not believe one can distinguish it from a carcinoma, but it is often a mul-

tipile lesion. I did not mention the possibility of a mass outside the colon surrounding it and pressing on it. The size of the mass and the fact that there was no bleeding would lead one to think of such a condition, but I do not believe it could destroy the mucosa to the extent that is present here.

DR. SWEET: Thus the fact that the mucosa had been destroyed, with evidence of ulceration, makes it appear that this was an intrinsic lesion of the bowel wall. I do not think we can go farther in discussing the differential diagnosis. At least, I cannot. Benign tumors, lipoma, myoma and so forth, would not fit the x-ray picture. Oftentimes, in my experience on exploring these doubtful cases, it is difficult by palpation or inspection of the lesion, to distinguish between neoplastic disease and tuberculosis. I think there is a little more evidence in favor of carcinoma than tuberculosis. That is as far as I can go.

DR. JOHN D. STEWART: What significance, if any, do you attach to the positive Graham test?

DR. SWEET: I noted it and meant to speak of it. I have excluded it in my mind because of the physical examination of the tumor. The tumor might have been the gall bladder pressing on the colon, but the remark is made that it was well below the liver edge, and also the x-ray film seems to put it away from the region of the liver. Of course, the kidney can be excluded because it was taken out, as was the appendix; but the patient did have that change from a negative to a positive Graham test, it is true.

CLINICAL DIAGNOSIS

Carcinoma of transverse colon.

DR. SWEET'S DIAGNOSIS

Carcinoma of transverse colon.

ANATOMICAL DIAGNOSES

Carcinoma of transverse colon, with perforation.
Pericolic abscess.

Polyposis coli.

Aspiration pneumonia.

Ileotransverse colostomy.

Operative scars: right nephrectomy; hysterectomy; bilateral salpingectomy, left oöphorectomy, appendectomy.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The patient was explored, and a very large mass was felt in the transverse colon, which was adherent to the liver, omentum and gall bladder. It seemed inoperable and an ileotransverse colostomy was done, short-circuiting the bowel about the lesion. In the course of the op-

eration, difficulty occurred in anesthesia, and a large amount of gastric contents was vomited and aspirated. The patient went promptly into severe shock. She never recovered in spite of two 500-cc. transfusions, and died in a little less than twenty-four hours. At post-mortem examination, the effort was made to free up the mass, and a large abscess cavity was broken into. This showed free communication with the bowel through a perforated cancer of the transverse colon. The peritoneal cavity was quite free from reaction, and the abscess had been very well walled off. The remainder of the autopsy showed extremely wet hemorrhagic lungs, with a great deal of edema and fulminating but incipient pneumonia. There was no evidence at the time of autopsy of any active tuberculous process in the lungs, the urinary tract or the bowel. Five or six polyps were found in the colon, besides the carcinoma.

CASE 27242

PRESENTATION OF CASE

A thirty-nine-year-old woman entered the hospital complaining of blood and pus in her stools.

The patient felt perfectly well until seven weeks before admission, when she first noticed blood in her stools. Several times a day for the next four days when she attempted to have a bowel movement, nothing passed but blood, each time amounting to half a cupful. Then the patient took a laxative, and watery movements colored with blood resulted. Thereupon she consulted her physician, who made a diagnosis of hemorrhoids and prescribed a local ointment and petrolagar. There was no improvement, however, and the loose bloody stools continued. Two weeks before entry the patient consulted another physician, who advised admission to another hospital. Here a hemorrhoidectomy was performed, and the patient stated that "an abscess was found above the hemorrhoids." A rectal tube was used for three days postoperatively, and it drained a purulent material. Thereafter daily enemas were instituted, and the patient found that she was incontinent of feces, which appeared to consist of nothing more than pus. The patient had not suffered from nausea, vomiting or pain, nor had there been weight loss, but on the fourth postoperative day she believed that she had had a chill followed by fever.

On examination the patient was flushed, acutely ill and dehydrated. The heart and lungs were normal, the blood pressure 95 systolic, 60 diastolic. The abdomen was tense, but not tender. No organs were palpable, but one examiner believed a mass might be present in the left lower quadrant.

Around the anus, which drained a foul purulent discharge, were radial scars, and no sphincter

could be felt. The rectal mucosa was redundant, thick and granular, and bled easily. The examiner believed a palpable resistance was present that corresponded to the mass he had felt in the abdomen and that this mass narrowed the lumen of the bowel which was otherwise freely patent.

On vaginal examination the cervix was found to be reddened, slightly patulous and soft; it oozed a purulent discharge, which contained three or four small pieces of red-black friable material. There was slight thickening in both vaults, and the uterus was enlarged to about four times its normal size and was hard and fixed, but not tender.

The temperature was 101°F., the pulse 100, and the respirations 20.

The urine gave a ++ test for bile. The blood showed a red-cell count of 3,410,000 with a hemoglobin of 70 per cent, and a white-cell count of 6600. The nonprotein nitrogen of the blood serum was 40 mg. and the protein 6.8 gm. per 100 cc., and the chlorides were 87.9 milliequivalents per liter. A blood culture and a blood Hinton test were negative. A Frei test was negative, the cervical culture was negative for Beta hemolytic streptococci and a culture of the anal discharge yielded *Pseudomonas aeruginosa*, but no pathogens. A biopsy of the rectal mucosa showed acute and chronic inflammation.

The patient's condition never improved, foul pus continued to drain from the rectum, and on the third hospital day her abdomen was distended, the temperature 103°F. and the white-cell count 8100. A flat abdominal x-ray film showed a large amount of gas in a dilated colon, the greatest dilatation extending from the cecum to the splenic flexure. Some gas was present in the descending colon, however. The presence of air under the diaphragm could not be determined definitely. On the fourth hospital day a cecostomy and appendectomy were performed. The cecum was found to be dilated and so tense that aspiration with a needle attached to a suction tube was necessary before introducing the cecostomy tube. Histologic examination of the appendix showed acute inflammation. Although the patient's abdomen was deflated on the following day and peristalsis was active, her temperature rose to 104°F., and the white-cell count dropped to 3150. Large quantities of foul, bloody material continued to escape from the rectum, with but little discharge from the cecostomy opening. Death occurred on the third postoperative day, seven days after admission.

DIFFERENTIAL DIAGNOSIS

DR. ALLEN G. BRAILEY: May we see the x-ray films?

DR. GEORGE W. HOLMES: These films confirm

the statement made in the text that there was no visible air below the diaphragm on either side and that the colon was enormously dilated. One gets a different impression from looking at the film than from reading the text, since the dilatation is much more than an ordinary one. The haustral markings are visible. It is a queer-looking colon for obstruction. No fluid is present. It seems to stop somewhere in the region of the splenic flexure. The bowel below the splenic flexure does not seem to be dilated although there is some air in it.

DR. BRAILEY: In discussing this case, we must answer two questions: First, What was the primary condition from which the patient was suffering, and, secondly, Why did she die? I prefer to answer the second question first. I think she died of overwhelming sepsis, a conclusion that is supported by the record of high fever, falling white-cell count and rapidly fatal course. The urine was said to contain a ++ test for bile, so that I conclude that her liver was seriously damaged, and it may well have contained multiple abscesses, metastatic from the rectal bed. It is not clear whether the patient had generalized peritonitis as well as pelvic peritonitis, which she certainly had. The abdomen was "tense but not tender." Apparently the service suspected intestinal perforation, for an attempt was made to demonstrate air under the diaphragm by x-ray study.

The primary condition was some fulminating, destructive and ulcerating lesion of the rectum. In deciding its nature, I think we should consider carcinoma, ulcerative colitis, lymphogranuloma inguinale, amebiasis, tuberculosis and perhaps some rare infection such as actinomycosis. This was another case of bleeding from the rectum that was not due to "hemorrhoids." In fact, operation in this case may have opened the way for fatal spread of the infection, for the patient appears to have been singularly free from any constitutional symptoms until shortly after the operation was performed.

There is something to be said in favor of carcinoma in this case. Rectal bleeding should always suggest the possibility of carcinoma. A left lower-quadrant mass was felt both through the abdominal wall and by rectum. The uterus is said to have been enlarged, hard and fixed, which might suggest extension of neoplastic disease from the rectum. But I find it impossible to believe that a woman of thirty-nine who had no evidence of ill health eight weeks before death could nevertheless have had cancer so widespread and so ready to break down that it could produce this picture of extensive ulceration and fatal sepsis, all within a relatively few days.

I am even more willing to exclude tuberculosis

of the rectum. It is not a very common disease in this part of the world at present. Its progress is usually slow and chronic, accompanied by the development of multiple fistulas. Certainly tuberculosis alone will not explain this very rapid course. Amebiasis requires a little more attention. It can occur in very acute form, and may be accompanied by the discharge of a great deal of blood and pus. The inflammatory process and even the amebic infection itself may spread to involve adjacent pelvic organs, and, of course, its tendency to produce liver metastases is notorious. Usually this severe form is accompanied by marked pain and tenesmus, but I cannot understand why this woman did not have bowel pain, whatever her diagnosis. But amebic infection is rare in this vicinity, and this is not the common picture of amebiasis, even when it does occur, so that I am inclined to discard amebic infection as a very likely possibility. Incidentally, the disease is rather commoner in the proximal than in the distal end of the large bowel.

I am left with idiopathic ulcerative colitis and lymphogranuloma inguinale. As a matter of fact, this is an excellent description of acute lymphogranuloma involving the rectum. Almost an identical case history is given by Roudaniche, Kirsner and Palmer* in a discussion and comparison of these two diseases. The free discharge of pus and blood is characteristic. A rather serious objection is raised by the report that a Frei test was negative. A Frei test properly performed and with a satisfactory antigen is quite specific. Of course, no laboratory test is infallible, and, in fact, a few very interesting cases have been reported of very ill persons with lymphogranuloma whose Frei tests remained negative until they began to improve. These negative results have been ascribed to a state of anergy. I am therefore not willing to exclude the possibility of lymphogranuloma because of a negative Frei test, but I do think it becomes improbable.

I think that this picture could have been due to fulminating ulcerative colitis. I confess I am puzzled that this patient presented no symptoms whatever except rectal bleeding until about two weeks before her death. I am surprised that she did not have colic, tenesmus and diarrhea, but I think that the lack of these symptoms is hard to explain on any basis. I suppose that the pathologic process must have been relatively mild during the first five or six weeks of her illness, with perhaps only a few ulcerations, which happened to bleed freely, and that shortly after her operation its virulence

suddenly mounted and secondary invaders began rapidly to destroy the mucosa and apparently even the anal sphincter. I do not know whether the anal sphincter was actually destroyed by the disease process or whether its function was interfered with in some way. The x-ray films seem more striking than I had thought they would turn out to be from the record, but I do not believe there was mechanical obstruction. I think this was perhaps ileus in a terribly sick woman.

DR. RICHARD H. SWEET: That degree of dilatation in the colon is not inconsistent with a fulminating ulcerative colitis.

CLINICAL DIAGNOSES

Perianal and pelvic abscess.
Septicemia.

DR. BRAILEY'S DIAGNOSIS

Acute idiopathic ulcerative colitis.

ANATOMICAL DIAGNOSES

Acute idiopathic ulcerative colitis, with perforation.
General peritonitis.

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: At post-mortem examination, a generalized peritonitis was found, with a perforation in the lower sigmoid just barely above the pelvic floor. When the large bowel was opened, it showed multiple areas of erosion, interspersed with polypoid hypertrophied fragments of the remaining mucosa extending all the way from the rectum to the cecum. When one held it up to the light, there were multiple areas where the wall of the bowel was only of paper thickness, and any one of a score of places might easily have perforated. There was no mechanical obstruction.

Nothing was found at autopsy to explain any palpable mass in the left lower quadrant. The uterus and adnexa were normal, and there was no evidence that there had been a localized pelvic abscess before the generalized peritonitis occurred.

DR. BRAILEY: What about the liver?

DR. MALLORY: It was negative grossly, and essentially negative histologically.

DR. BRAILEY: Why was the patient jaundiced?

DR. MALLORY: It was not apparent that she was.

DR. BRAILEY: How could she have a ++ test for bile without being jaundiced?

DR. MALLORY: I do not have any answer to that.

DR. JOHN D. STEWART: It is a fairly rough test.

DR. BRAILEY: Yes; I think that it is.

THE BISHOP'S POSTSCRIPT

IN March, 1939, the Right Reverend William Lawrence, former bishop of the Protestant Episcopal Diocese of Massachusetts, then nearing his ninetieth year, issued his postscript. Long a tiller of the soil from which are harvested the fruits of men's labors, he prepared a new field for the harvest. Over his own signature and in his own hand, under the title "My Postscript," he penned, not laboriously but with infinite patience, some fifteen hundred letters; these letters went to as many friends of the Massachusetts General Hospital,—“doctors, nurses, workers in all departments of the hospital, as well as patients; old friends of the hospital and new friends, rich and poor,”—and the purpose was to unite them in one enterprise: the building of a chapel within the hospital.

This chapel, as the Bishop visualized it and as he then expressed its use, would be not a church or a temple or even a chapel in the ordinary sense, for its purposes would transcend those of such denominational structures. Since the hospital opens its doors to succor those of all faiths, races and traditions, so also should a chapel, itself cloistered within the walls of the hospital, afford to those of all faiths, races and traditions a place of spiritual refreshment.

The enterprise prospered, with its significant appeal, quietly and surely. By the fall of 1939 over fifty thousand dollars had been pledged by more than eight hundred persons—one ward of the hospital sent four dollars and thirty cents, with the signatures of forty-one patients.

Soon thereafter the work was in progress, and in April, 1941, without ceremony, the doors of the chapel were opened that all might see its simple, lofty dignity and the rich coloring of its windows and might appreciate it as a place of peace and sanctuary.

As has been said before, the chapel is not a church, for a church implies religious denominationalism. The inspiration and the work of a Christian ecclesiastic, it is dedicated to the use of all who recognize and seek the help of a power greater than themselves; in a great house of physical healing it is a small chamber for spiritual healing.

Such a chapel, representative of all faiths in general, and of no faith in particular, is fittingly erected in a country that has dedicated itself in principle to freedom of thought and of worship, and to equality of opportunity. It is perhaps also significant that there has been faith to build such a structure for permanent use, in a time when destruction apparently reigns supreme.

HEALTH OF THE NATION AND NATIONAL DEFENSE

No one doubts that the national health is inextricably linked with the national defense. Only a healthy and united nation can hope to prepare and carry forward an adequate military program

under present-day circumstances. Nor is there much doubt—some authorities to the contrary—that a disproportionately large percentage of men called under the Selective Service Act are rejected on grounds of physical or mental defects. On the average, approximately 60 per cent of all men in Massachusetts are now being rejected by the physicians of the local selective-service boards, and, of those passed as fit for full military duty, an additional 18 per cent are turned down by induction-board physicians acting directly under the United States Army. Both boards are guided so far as physical requirements are concerned by official regulations (M. R. 1-9), and it is misleading to say that “the point of view of the army and civilian medical examiners might be expected to vary considerably concerning the acceptability of certain risks.”¹ Within reason, the rules and regulations are clear and definitive.

It therefore appears that, at least in Massachusetts, over 70 per cent of all men otherwise available for the Army are being rejected for physical or mental defects. Surgeon General Parran has correctly termed this a “national disgrace.” The problem of national health is a challenge to the medical profession. It is idle to argue that the Army regulations are unduly strict; for in modern warfare there is no place save for those who can “take it.”

On the other hand, it is comforting to know that the tuberculosis rate (standard x-ray films of the chest are taken of all men inducted in Boston) has dropped to the comparatively low rate of 0.5 per cent,² and it is of interest to note that rate of rejection for cardiovascular disease among men already passed by their local boards is almost precisely the same as it was in the last war (0.8 per cent as compared with 1.0 per cent).³ It is discouraging, however, to find that nearly 5 per cent of all men sent as physically and mentally fit to the Induction Center in Boston were subsequently rejected because of neuropsychiatric abnormalities and that from 5 to 10 per cent were returned to their homes because of insufficient teeth. Detailed figures of rejections by the local-board physicians are not available for the entire

induction period, but it is disturbing to note that of the first 3000 men examined nearly 15 per cent were rejected because of dental defects and that a very considerable percentage of all causes of rejection by the local-board physicians might properly be regarded as preventable or remediable.

“After all,” says one authority, “what can be done for flat feet, bow legs and perforated ear drums?”⁴ The implication seems to be that these causes for rejection could not have been prevented and that the medical profession has done its best, for better or for worse. It is true that little or nothing can be done for a long-standing perforation of an eardrum,—once it has occurred,—but many such chronic disabilities could have been prevented by the medical profession; bowlegs—which, incidentally, are not a cause for rejection—would never have developed under proper child hygiene, and certainly the disability arising from “flat feet” can, with a little judicious advice, be adequately and completely corrected in many cases.

Why “whistle in the dark”? Seventy per cent of the young men in this country are being judged by proper authorities to be physically unfit for “full military service.” It is for the medical profession on the one hand and the laity on the other to see to it that this percentage is materially reduced, not only in times of war but also in times of peace.

MEDICAL EPONYM

HORNER'S SYNDROME

Johann Friedrich Horner (1831-1886), professor at Zurich, published an article “Ueber eine Form von Ptosis [Concerning a Form of Ptosis]” in the *Klinische Monatsblätter für Augenheilkunde* (7: 193-198, 1869). A portion of the translation follows:

Six weeks after the last pregnancy that occurred a year before I saw her, the patient noticed a gradual drooping of the right upper eyelid . . . the pupil of the right eye was found to be definitely smaller than that of the left, the eyeball very slightly sunken. . . .

While the case was under observation, there developed before our eyes gradually increasing redness and heat of the right half of the face, although the left half remained pale and cold. . . . The patient then told us for the first time that she had never perspired on the right side. . . . I believe that in view of all these symptoms no one will question my opinion that this gradually developing, but never complete, ptosis should be regarded as a paralysis of the superior palpebral muscle, which is supplied by the sympathetic. I thus regard the phenomenon in the upper lid as a part of a larger symptom-complex.

Boston

HEMORRHAGE AND SHOCK ASSOCIATED WITH CESAREAN SECTION AND FOLLOWED BY DEATH

A forty-year-old para II was first seen in the thirty-ninth week of her pregnancy by the physician who delivered her. She had moved into his neighborhood recently, and previously had presumably received adequate prenatal care. Her first question was, "Will you deliver me by cesarean section? I have such a horror of my first delivery that I just can't bear the thought of going through labor again."

The past history was irrelevant. The first pregnancy two years previously had terminated in a forceps delivery of a living child.

The patient was seen only once before delivery. At that time, physical examination disclosed a well-developed and well-nourished woman. The heart was not enlarged; there were no murmurs. The lungs were clear and resonant; there were no rales. The blood pressure was 120 systolic, 65 diastolic. The abdomen was enlarged to a size consistent with her dates; the fetal heart was audible.

An elective classic cesarean section was performed before labor started, nitrous oxide, oxygen and ether being used as the anesthetic. Two hours after delivery, the patient died from hemorrhage and shock. The abdominal dressing was soaked with blood, and there was reported to have been a good deal of vaginal bleeding.

Comment. One does not expect to see fatal post-partum hemorrhage in elective cesarean section, and in well-trained hands death from this

cause two hours after delivery is inexcusable. The main point to be brought out discussing this case is that cesarean section still carries hazards. It is not an operation to be undertaken without appreciating these hazards, and to do cesarean section because a patient states that she cannot stand the pangs of labor is absolutely unwarranted in this day of comparative freedom from pain afforded by modern analgesia.

WHAT A HEALTH EXAMINATION MEANS†

A hundred years ago, when Mr. Jones called in the doctor we knew that he must be very sick, perhaps dying. In those days people did not consult the doctor until they were in real trouble. Yet almost one hundred years ago, in 1850, to be exact, a prominent Bostonian, Lemuel Shattuck, was advocating a measure that called for visits with the doctor when one was not sick at all. At that time, typhoid fever, malaria, smallpox, diphtheria and similar plagues were rampant. The important advances to be made were clearly in the field of public health. Mr. Shattuck believed, nevertheless, that more attention should be paid to personal health; that people should be encouraged to have frequent "sanitary examinations" made of themselves in an effort to promote their health and to prevent disease.

Since that time, there has been a growth of the idea in certain directions, yet there seems to be a lack of enthusiasm for it on the part of the people in general and to some degree within the medical profession itself—the laymen, perhaps because it seems unnecessary to go to the doctor when one is perfectly well; some doctors, because they may think that there is not enough to be accomplished by such measures. Modern medicine surely should not be, as it has been in the past, primarily engaged with death, pain and disease, but should concern itself more with health, happiness and life.

Legend has it that the ancient Chinese paid the doctor so long as the patient remained well. Yet experience shows us that although many Orientals may live to a ripe old age, they all seem to reach the same eventual state of physical dissolution, whether they have paid the doctor to keep them well or not. Now the question is, it seems to me, whether or not such a thing as a periodic health examination can be of any real value in helping us to lead healthier, happier and longer lives.

As a matter of fact, infants and young children have examinations at fairly frequent intervals. Children of school age in many parts of this country, through the agency of the school physician and school nurse, are given some kind of a health check-up at intervals. Many adults undergo an examination when they apply for life insurance. In industry, clinics have been set up for examination of employees. There remains a tremendous group of people, nevertheless, not reached through these channels, people who have no family physician and who lack the initiative to seek out a physician in whom they can place their confidence and to whom they can turn for medical advice.

It seems to me that every adult ought to have a doctor who knows him as an individual person and who has more information about him than mere data regarding his age, weight, blood pressure, and so forth. We are all

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

†A "Green Light to Health" broadcast given through Station WAAP by the late Dr. Michael F. Murray, Jr., on Tuesday, December 17, 1940, and sponsored by the Public Education Committee of the Massachusetts Medical Society and the Massachusetts Department of Public Health.

going to need the doctor some time, and calling on a physician who has known us and who has examined us in the past is much more satisfactory from the point of view of both patient and physician than a situation in which an acutely sick person has a strange physician see him for the first time.

Another obvious consideration, of course, in having such a relation with a personal or family physician is that he gives us a thorough examination at the beginning of the relation and re-examines us from time to time for the purpose of discovering physical defects or the signs of early disease, and in general helping us in any way that he can to maintain a state of good health.

It might be well to discuss briefly what such an examination entails. The physician will ask something of one's family history, inquire into the details of one's past illnesses and will also determine whether or not one is having any difficulties at the time of the visit. He will then proceed to make a careful examination which will include the skin, eyes, ears, nose and throat, heart, lungs, abdomen, the determination of blood pressure, a search for any unusual lumps and so forth. The doctor will also take a urine sample for analysis, and may do a blood test.

My conviction is that too much stress cannot be laid on the value of the history. In recounting the illnesses, accidents, operations and trials of our past lives, we may very well give information of great importance, although it may not appear to us to be of any particular significance. In this connection, I think it is well to remember that the things we tell the doctor are held in confidence by him and there is nothing to be gained by concealing something that may be difficult to talk about. Frequently a good talk with the doctor will help straighten out troubles that are rooted in worry, fear or discouragement. Emotional difficulties, although they may not kill us, can without any doubt make us just as sick and ineffective as the grossest kind of organic disease. An organized set of emotional difficulties, by the way, has a name; it is called a neurosis. There are times when the wise family doctor can do much to help us maintain a solid emotional balance.

To get back to our examination after the history is taken, a careful physical examination is made, including the procedures already mentioned. I also believe that a Wassermann test or one of its modifications should be done. Further blood examinations may not always be necessary, but a hemoglobin determination and an examination of a blood smear ought to be included in most cases. The white-cell and a red-cell count should be determined, if indicated. In the event that these are all normal, they serve as a base line for comparison if any of them change later in life.

After these things have been done, the doctor will discuss the results of the examination with the patient and will answer his questions as adequately as possible.

Most of us will be found to be in fundamentally sound health or to have only some minor deviation from the normal. We then have the assurance that within the limits of such an examination we are in a state of good physical health.

Sometimes, of course, the physician will find the existence of definite disease and will recommend treatment, or he may find some suspicious signs for which he will ask us to report later for further observation or recommend further immediate investigation such as chest, stomach or intestinal x-ray study, blood chemistry de-

terminations or an electrocardiogram, these things being done, of course, only when indicated. A metabolism test may in some cases be recommended.

There is no reason to believe that our family doctors are unable or unwilling to take the time and pains to do a good job. Some of us may still have a picture of the family doctor as a kindly old gentleman with long whiskers who lurches Dobbin to the gatepost, comes in for a visit and hints his examination to a look at the tongue and a pat on the back. I suppose such ideas make some people prefer to place themselves in the hands of a so-called "health institute."

I know that we can find plenty of well trained physicians who are going to give us careful and competent attention, men in whom we can place our confidence. I believe that every adult ought to have such a physician as his own doctor and that a careful examination should be done at the beginning of this relation. If the person subsequently becomes ill or has some symptoms that worry him, he should report to this same physician. If he remains in a state of good health, he ought to continue to see his physician from time to time—probably best, every year, but certainly, every few years. I prefer to see my doctor every year.

If expert advice or some of the more complicated laboratory procedures are needed, our physician can help us in securing the services of the appropriate specialist. He can also be of tremendous help to the specialist in furnishing background information so necessary for the intelligent evaluation of our particular problem. In this way we can be sure that so far as the present state of the art and science of medicine goes we are getting the best. If we happen to be somebody who has a limited income we can be thankful that we live in this country where through one channel or another good medical care can be had by all. But we have to go and get it. It will not just come to us.

One may ask what kind of abnormality might be discovered at such an examination. Quite a few things might be found although if many of them existed to any serious degree the patient would probably have some kind of symptoms. One of the various anemias might be found. Sometimes the finding of a definite degree of anemia leads to the discovery of some underlying cause. Tuberculosis in its earliest stages is usually not detectable by physical examination of the chest, and would not be discovered unless it were sufficiently advanced that the patient had some symptoms or some definite physical signs. Any suspicious symptoms, such as persistent cough or the inability to maintain normal weight would lead the examining physician to recommend an x-ray examination of the chest for diagnosis. Certain types of early cancer might also be discovered. When such a discovery is made, appropriate treatment can be given with a good chance for complete cure, whereas cancer in an advanced state, as we know, is not nearly so amenable to treatment.

I recently heard of a woman in her forties who, in the course of a routine physical examination was found to have a small ulcerated area. It was smaller than a dime. A small specimen was taken from the region and was found to be suspicious of early cancer. She is having well planned treatment and her chances of getting complete relief are almost 100 per cent. A number of other conditions that might be uncovered are high blood pressure, certain types of heart disease, chronic Bright's disease and diabetes. Complete cures for some of these maladies are not known, but in some conditions such

as diabetes, the physician can prescribe treatment that will make a long and useful life possible when neglect of the disease would be disastrous. In certain other diseases, modification of one's mode of life, especially with regard to work, diet, exercise and rest, may be of the utmost importance.

One drawback might, I think, be mentioned. An examination that reveals no evidence of ill health may sometimes create a false sense of security. It must be remembered that the physician is not an omniscient being and that some diseases have an insidious beginning, sometimes existing in an early stage without presenting symptoms or signs, and not being apparent even after the most painstaking examination.

Why, then, do we advise these examinations? I think that a question of this nature can be answered best by summing up the points that I have previously tried to make. First of all, I think that we all ought to have a complete examination early in adult life to determine whether or not we have any physical defects or whether we have the early signs of disease. We ought to have such basic information so that we can correct any defects that are amenable to treatment. If we are found to have some condition for which there is no complete cure, we can then, at least, have competent advice in the regulation of our daily lives. Secondly, we should, each one of us, establish a relation with a doctor whom we choose as our physician and medical adviser and whom we can consult subsequently either because of illness or for advice about many of the knotty problems that are bound to vex us from time to time. It is far better to turn to an intelligent physician who has some common sense and both feet on the ground than to take our medical advice from well-meaning neighbors, faddists and cultists.

In conclusion, may I re-emphasize my belief in the importance of having a personal or family physician? Let him give you a thorough examination. Let him see you from time to time. Once a year is not too often. Get your advice about health problems from him. Let him, in what ways he can, help you to keep well, and in time of illness, call on him.

DEATHS

GILMAN—BERNARD B. GILMAN, M.D., of Boston, died May 31. He was in his thirty-eighth year.

He attended Harvard College and received his degree from Harvard Medical School in 1929. Dr. Gilman was assistant director of the division of communicable diseases of the Massachusetts Department of Public Health. In 1938 he received the degree of master of public health at Harvard.

He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow, two sisters and five brothers survive him.

HAIGIS—PETER J. HAIGIS, M.D., of Foxboro, died June 2. He was in his sixty-ninth year. Dr. Haigis received his degree from Boston University School of Medicine in 1904. He was a member of the Massachusetts Medical Society and the American Medical Association.

REPORTS OF MEETINGS

HARVARD MEDICAL SOCIETY

There was a regular meeting of the Harvard Medical Society on March 11, with Dr. Elliott C. Cutler presiding. The first case was that of a forty-nine-year-old man who had had, over a period of seven weeks, a gradual onset of painless jaundice, with anorexia but no nausea or vomiting. There had been fleeting right upper-quadrant pain on one occasion three weeks previously. The stools had been light in color, and there had been periodic dark urine. Physical examination revealed marked jaundice, weight loss and an enlarged nontender liver. The chief positive laboratory findings were an elevated icteric index and cholesterol, and clay-colored stools, which were strongly guaiac positive. The prothrombin time was increased, and a gastrointestinal series revealed a filling defect of the duodenum. The patient was started on a regimen of parenteral glucose and vitamin K, but developed a sudden fever on the second day, with a positive pneumococcus blood culture. Treatment with sulfathiazole reduced the fever and the number of colonies on blood culture, but there was still evidence of a bleeding tendency, and blood transfusion and vitamin K were undertaken to return the red-cell count and prothrombin level to normal. Dr. Soma Weiss suggested that the case was probably one of primary neoplasm of the head of the pancreas. Dr. Samuel A. Levine commented that the early detection and intensive treatment of pneumonia may prevent the onset of the characteristic pulmonary manifestations of the disease.

The second case was that of a seventy-two-year-old man who for two or three years had experienced indigestion, gaseous eructations and an idiosyncrasy to fried and fatty foods, all of which were relieved by a proper diet. For the previous six months, there had been an exaggeration of all symptoms, with severe right upper-quadrant pain, nausea and vomiting. Physical examination revealed a dehydrated, questionably jaundiced elderly man, with a large tender right upper-quadrant mass, a leukocytosis of 21,000, an icteric index of 18, a negative diastase test and a slightly increased prothrombin time. On conservative treatment, the abdominal mass diminished in size. A gastrointestinal series was essentially negative, a cholecystogram revealed a nonfunctioning organ, and there was bile in the urine, an increased urobilinogen and occult blood in the stools. The patient was given 10 mg. of vitamin K preoperatively, and when cholecystectomy was carried out, small stones were found in all the ducts.

The speaker of the evening was Dr. Israel S. Ravdin, who discussed "Some Aspects of the Physiology of the Liver and Biliary Passages." Dr. Ravdin compared the liver function to that of a food commissariat. For carbohydrates this organ is the place of synthesis and storage of glycogen, which is the sole source of metabolized glucose. Most of the liver-function tests based on carbohydrate metabolism have been found unsatisfactory either because they remain normal until there is a large percentage of damage (as in the glucose-tolerance test) or because they add nothing to the clinical diagnosis (as

in the galactose test) The protein functions of deamination and the synthesis of serum protein, fibrinogen and prothrombin are now assuming greater importance. There can be as high as 90 per cent destruction of liver tissue, with maintenance of normal deamination. The liver is the largest store of bile protein, and probably the entire source of plasma protein. A decrease in the body protein is evidence of hepatic insufficiency, except in the presence of anemia and nephritis. The liver is the sole source of fibrinogen, which is decreased only in late toxic processes. For the synthesis of prothrombin, the presence of bile salts in the gastrointestinal tract is necessary for the absorption of vitamin K.

The bile metabolism is the most sensitive mechanism but offers technical difficulties in its tests. The liver is involved in the synthesis of bile salts, the formation of cholesterol in the bile and the manufacture of bile pigments. A diminution of bile salts in the gastrointestinal tract may easily cause symptoms through impairment of its functions in the emulsification of fats, the activation of lipase, the increased motility of the intestine, and the increased absorption of the fat soluble vitamins. Pigment probably comes largely from the blood, and the site of synthesis is more probably in the reticuloendothelial system of the liver and spleen than in the bone marrow. Dr Ravdin suggested at this point that a ten day study of stool specimens for urobilin may be a means of differentiating carcinoma of the head of the pancreas from an obstructing stone, for in the latter this substance will be found in at least some of the samples.

The detoxifying function of the liver has been used in the hippuric acid test to measure hepatic competence, but a normal test may be found with liver destruction of 70 per cent. Among the excretory functions are those associated with the bile pigments and other dyes. The bromsulfalein test is the most sensitive test of excretion. It was concluded that a combination of all these indices offers a clue to the liver function, which may or may not be substantiated by the subsequent course. In the treatment of increased prothrombin time, it was found that approximately 70 per cent of patients responded to both the natural and synthetic vitamins.

Studies on various types of bile indicate that normally the calcium, chloride and bicarbonate contents are similar to that of serum, whereas the cholesterol is not esterified. In the gall bladder, or storehouse, bile and esterified. In the gall bladder, or storehouse, bile salts are concentrated while the acid components are decreased. In gall bladder disease this concentration and decreased, respectively, are not maintained, although in severe affections there may be an actual increase of fluid and an inversion of the expected ionic relations. These in conditions offer a nidus for stones, for cholesterol is in equilibrium only when salts are present in proper amounts.

It was pointed out that in cholecystograms one should observe granules of opaque substance in the ascending colon to make certain that the gall bladder has had an opportunity to excrete the dye, for this is also excreted normally in the ascending colon.

As evidence that sensory stimuli from the gall bladder may simulate cardiac pain, three cases were cited of a proved interrelation of anginal symptoms with stimuli from the gall bladder region.

As the result of studies on the protection of the liver from toxic substances, the old concept of employing high carbohydrate and low fat diets has been supplanted. It was determined that the degree of hepatic injury is roughly proportional to the lipid content and that a high glycogen content offers no protection if this level is high

enough. An increased protein on the other hand, although it fails to prevent liver damage, does halve the amount of necrosis. It was found during the course of these experiments that a sterile fixation abscess produced with sodium ricinoleate prevents hepatic injury to any extent with any toxin. Oral protein does not have this effect because the circulating protective agents are formed only when the toxin is administered, instead of before that time. Any sterile abscess will have the same effect, the main problem being to rid the liver of fat at the expense of protein. In regard to the proper preoperative and postoperative management of biliary cases, it was pointed out that forced feeding, with emphasis on carbohydrates and vitamins is the best regimen for preserving glucose and diminishing lipids. Intravenous glucose is insufficient even for caloric requirements, and serves only temporarily to spare the protein stores of the body. The reappearance of the synthesis of bile salts following a common-duct operation may take many days, and bile feeding should be carried on during this entire period. If these salts remain low for more than twenty days, the patient will undoubtedly remain dyspeptic, owing to poor biliary function. It has been shown that the best protein for liver regeneration and protection is casein, whereas gelatin is the worst.

ALPHA OMEGA ALPHA

At a regular meeting of the Harvard Chapter of Alpha Omega Alpha on March 13 Dr Israel S. Ravdin gave a companion discussion on 'Preoperative and Postoperative Care of Patients with Biliary Tract Disease'. It was pointed out that the mortality entailed in such surgery is in large part due to ill advised or poorly administered preoperative and postoperative care. In considering the preoperative condition of the patient, one should remember that as little as 15 per cent of good liver tissue is adequate for normal values in most liver function tests, thus incipient incompetence may be overlooked, and a patient thrown into insufficiency by the relatively minor trauma of the operation and anesthesia. Moderate or even severe cardiac disease especially if demonstrable only by the electrocardiograph, should not be considered a contraindication to biliary tract surgery, if the local indications are clear, for it has been amply demonstrated that such operations may be followed by disappearance of certain pathological electrocardiograph findings.

The incidence of diabetes mellitus in chronic gall bladder patients is double that of the general population and may lead to easy hypoglycemic shock in such people under insulin treatment, for their liver glycogen store—a measure of function—is invariably lowered.

The hemorrhagic diathesis of obstructive jaundice is now known to be associated with a decreased prothrombin level, which is conditioned by poor absorption of vitamin K from the intestinal tract in the absence of bile salts. Certain patients—probably those with severe liver injury—are unresponsive to any form of vitamin K therapy, and this number of complete failures is about 18 per cent. 2-methyl-1, 4-naphthoquinone has been proved one hundred to one thousand times more potent in restoring the prothrombin time to normal than the naturally occurring vitamin K. The prevention of a hemorrhagic tendency lies in frequent prothrombin time determinations, the administration of vitamin K substrates with bile salts preoperatively and for ten to fourteen days postoperatively, and transfusions of blood high in prothrombin value, when other measures fail. It was emphasized that hemorrhages may still occur after jaundice has disappeared.

Another factor that may materially alter the mortality

is the decrease of liver damage by the choice of suitable anesthetics and the preoperative liver build-up. Probably any inhalation anesthesia causes some injury, and anoxia and chlorine derivatives produce the most damage. Therefore, the condition of the liver at the time of operation is the most important conditioning factor. It has been amply demonstrated that a liver high in available protein and low in lipid content affords the maximum protection against liver necrosis, if not damage. The deposition of liver glycogen is advantageous only if it displaces fat and protects the liver stores. Preoperative starvation tends to cause a high-lipid, low-protein content, and no amount of glycogen can protect a liver in which the fat content is above normal. Parenteral glucose alone cannot maintain adequate hepatic stores, and one should strive to force a high-protein, high-carbohydrate diet as soon as possible postoperatively. A diet consisting of 70 to 75 per cent carbohydrate, 20 to 25 per cent protein and less than 5 per cent fat offers the best conditions to combat damage and favor repair of the liver. The diets should be individualized for taste. Cottage cheese, with its high casein value, has been found an excellent food, and bananas have also been extensively used. Patients are given a 2600 to 4000 calorie diet a day and are actually forced to eat. Re-enforcement with plasma and intravenous fluids is helpful and sometimes necessary when patients are unable to retain food administered orally.

The only advice issued concerning the operative technique was to reveal accurately the vascular as well as the ductal systems, so that injury to or ligation of an anomalous hepatic artery, a procedure that inevitably results in death from liver insufficiency in experimental animals could be obviated.

Postoperatively, it is essential not to allow bile to be lost to the exterior in view of its important extrahepatic functions. Parenteral fluids cannot replace this loss. An attempt should be made to force it back into the duodenum by keeping the catch bottle at body level immediately after the operation, and then, by raising the bottle later, gradually to overcome the tonus. If this cannot be accomplished, bile should be fed. This can be done by collecting the bile when it begins to appear normal and then lyophilizing it.

The second important postoperative procedure is the early feeding of proper diets as described above. During regeneration, nucleoprotein is most important, and consequently the casein should be supplemented with large amounts of purines, especially liver. Finally, cholangiograms should be performed early so that immediate reoperation may be carried out in the event that a common-duct stone may be removed early, rather than caring for a stricture later. There may be enough residual liver damage in cases of long-standing disease so that there is temporary or even permanent decrease of gastrointestinal function as a result of decreased bile salts. When this diminution occurs, indigestion will remain after the gall-bladder colic has disappeared. In conclusion, Dr. Ravdin cited his mortality of 1.5 per cent in 604 cases for a ten-year period of all cases that were nonmalignant or not previously operated strictures. The decrease in mortality of comparable cases since the introduction of these newer preoperative and postoperative concepts was the most striking feature.

NOTICES

ANNOUNCEMENT

DR. HENRY L. CABITT announces the removal of his office from 475 Commonwealth Avenue, Boston, to 520 Beacon Street, Boston.

EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

Examinations for appointments as assistant surgeon (lieutenant, junior grade), United States Navy Medical Corps, will be held at all the large naval hospitals: the Navy Medical Center, Washington, D. C., on August 11 to 15, inclusive, October 6 to 9, inclusive, January 5 to 9, 1942, inclusive.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty but less than thirty-two years of age at the time of acceptance of appointment, and graduates of Class A medical schools who have completed at least one year of intern training in a hospital approved by the Council on Medical Education and Hospitals of the American Medical Association.

Examinations for appointment as acting assistant surgeon for intern training in naval hospitals accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association will be held on June 23 to 26, inclusive, October 6 to 9, inclusive, and January 5 to 9, 1942, inclusive. Applicant for appointment as acting assistant surgeon for intern training must be citizens of the United States, more than twenty-one but less than thirty-two years of age, and men of the junior or senior classes in Class A medical schools. After twelve months of intern training, acting assistant surgeons may apply for appointment as assistant surgeon in the United States Navy.

A circular of information regarding these examinations, physical requirements, rates of pay and promotion and retirement data may be obtained from the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., on request. Applications for authorization to take the examination must be received at the Bureau of Medicine and Surgery three weeks before the examination.

Medical officers of the United States Navy are encouraged to develop a specialty, and are assigned, if their interest in the specialty warrants such action, to postgraduate instruction in the large naval hospitals, the Navy Medical Center, Washington, D. C., and civilian medical centers. Some of the specialties in which medical officers may seek qualifications are: surgery, medicine, ophthalmology, otolaryngology, roentgenology, laboratory, pathology, public health, psychiatry, deep-sea diving, aviation medicine (flight surgery), gas warfare, tropical medicine, medical research and so forth.

BOOK REVIEWS

Controlled Fertility. An evaluation of clinic service By
 Regine K. Sax, M.D., and Frank W. Notestein, Ph.D. 8",
 cloth 201 pp., with 56 tables and 16 illustrations. Balti-
 more: William and Wilkins Company, 1940 \$3.00

This is the most important, original study of clinical
 contraception ever made in this or any other language.
 Dr. Sax, a physician on the research staff of the Milbank
 Memorial Fund, started to follow up a thousand women
 who had visited the Sanger Bureau from the Bronx in
 1931 and the first half of 1932. She located 991 patients
 interviewed them personally and secured a detailed and
 complete history. After a description of the group stud-
 ied and a consideration of the representativeness and ac-
 curacy of the data, the authors lunched it once into the
 reproductive experience of the group prior to clinic at-
 tendance. It has long been suspected by competent stu-
 dents of contraception that the early estimates by some
 clinic physicians of the reliability of contraceptives in
 preclinical use were worthless. Here it is shown that such
 "untutored" or "folk" practices are extraordinarily re-
 liable varying in effectiveness from 86 (condoms) to
 61 (douches) per cent. It is interesting that after patients
 abandoned the clinic method for one more acceptable to
 their individual needs, they practiced their habitual forms
 more effectively than prior to the clinic visit.

More than 40 per cent of the couples started practicing
 contraception immediately after marriage. After the first
 pregnancy the proportion doubled, and continued to in-
 crease as the duration of marriage lengthened. Couples
 more recently married took up contraception sooner than
 older couples. White collar workers used folk contra-
 ceptives much more effectively than laborers. Had the
 average couple not restricted family size in the nine
 years of married life preceding the first clinic contact,
 the wife would have had five pregnancies. Since al-
 most all couples used some method relatively early, the
 effectiveness was such that the average number of pre-
 clinical pregnancies per woman was only three. Only
 70 per cent of the pregnancies resulted in live births. 20
 per cent of the women were illegally aborted.

It has been demonstrated several times before that as
 pregnancies increase the risk of induced abortion is
 greater. Here there is confirmation of the fact. The
 rate for first pregnancies was 5 per cent, for pregnancies
 after the fifth, 50 per cent. Almost 40 per cent of the
 patients had accidental pregnancies in the two years im-
 mediately preceding their initial clinic contact. This
 was one of the circumstances that brought them to the
 clinic. They not only wanted a more reliable method but
 one that would permit more satisfactory social relations.

Most of the women who discontinued the clinic prescrip-
 tion did so within a month. At the end of that time only
 69 per cent were still using the clinic's prescription ex-
 clusively and regularly. Another 15 per cent were using
 it in part or alternating it with a habitual method. By
 the fifteen months slightly over a third were using the clin-
 ic's method exclusively and less than one half were using
 any part of it.

The high effectiveness of the clinic prescription is dem-

onstrated by the fact that there were only 9 pregnancies
 in each 100 years of exposure for the whole group. But
 it is a new finding of this book that the rates of effec-
 tiveness of variations of the clinic method 'did not differ
 significantly from those for the continuous and exclusive
 use of the prescribed contraceptives. Pregnancy rates
 with each kind of contraceptive after the patients at-
 tended the clinic were only half as high as the rates for
 the same devices prior to clinical attendance.

There are many practical tips in this book for the busy
 practitioner who has to deal with contraception. One is
 that it is much more important to induce a patient to
 adopt a method that will be continuously used than to
 urge the vaginal diaphragm and jelly on those who pre-
 fer another method. In other words, the absolute effec-
 tiveness of the method is less important than its acceptabil-
 ity to the patient.

The chapter 'Birth Control and Population Trends,'
 is brilliant and on the whole, sound. There might be
 differences of opinion among experts with reference to the
 interpretation of certain details, but the broad outlines of
 the position there taken are certainly well founded.

The fifty six tables and sixteen illustrations in this book
 assist materially in telling its story.

*The Extra Ocular Muscles. A clinical study of normal
 and abnormal ocular motility* By Luther C. Peter, M.D.,
 Sc.D. LL.D. Third edition, thoroughly revised 8",
 cloth, 368 pp. with 147 illustrations and 5 color plates.
 Philadelphia: Lea and Febiger 1941 \$4.50

The third edition of *The Extra Ocular Muscles* is ar-
 ranged in six parts dealing respectively with anatomy and
 physiology, heterophoria, concomitant squint, paralytic
 squint, nystagmus and surgical technique. Important ad-
 ditions have been made to Parts III, IV, V and VI.

In Part III which deals with concomitant squint, the
 author stresses the importance of the earliest application
 of measures to combat amblyopia, to correct anisometropia
 and aniseikonia, and to assist by orthoptic training in the
 development of the fusion faculty and he reviews the
 indications for surgery on the eye muscles.

In Part IV dealing with paralytic squint, a valuable
 section is devoted to a discussion of palsies of supranuclear
 origin.

Part V written by the author in collaboration with
 Dr. Joseph C. Yaskin professor of neurology at the
 Graduate School of the University of Pennsylvania, ana-
 lyzes clearly the ocular vestibular, and neurologic origins
 of nystagmus and suggests the value of using the ocular
 micrometer in the corneal microscope and slit lamp for
 the careful study of the character and amplitude of
 nystagmus.

In Part VI, dealing with surgical technique, the author
 frankly appraises the value of surgical procedures, and
 adds his comments about ptosis operations, and his meth-
 od of resection of ocular muscles to expedite surgery for
 retinal detachment and for exploration of the orbit in
 cases of neoplasms.

Blood Pressure Study 1939 4", cloth 69 pp. New York,
 compiled and published by The Actuarial Society of
 America and The Association of Life Insurance Medical
 Directors 1940 \$4.00

This volume consists almost entirely of mortality ta-
 bles based on nearly 50,000 deaths corresponding to
 about 1,309,000 life insurance policies. Of greatest inter-
 est are those showing the ratio of actual to expected deaths
 from various causes. Tables G to M show that the higher

a man's blood pressure at the time he takes out life insurance the greater are his chances of subsequent death at any given age from cardiovascular renal disease, cirrhosis of the liver, cancer, pneumonia or tuberculosis. The likelihood of his committing suicide, however, is progressively less the higher his blood pressure when he paid his first premium (Table N). Does this mean anything, and if so, what?

Properly understood and evaluated, life-insurance mortality studies are of very great value. Those who compile them would be quick to agree, however, that the process of drawing clinical conclusions from them is full of pitfalls for the unwary. Long ago, a comparison of European insurance mortality figures with those collected by American companies indicated that American men lived much longer than European men. Although this may have been due in part to the salubrity of our climate and form of government, Emory McClintock pointed out that one potent cause of the great difference was that, whereas European offices generally awaited applications, which are commonly prompted by some sense of need for insurance, the custom of American companies was (and is) "actively to solicit business through agents." On the average, he said, men who are induced only by persuasion to insure their lives are better risks than those who voluntarily apply.

There are many other factors to be considered in the evaluation of insurance mortality figures besides the effect of selection of risks. In the present connection, for example, one might raise the question of the validity of causes of death derived from death certificates, or the extent to which the transient blood-pressure level may be treated as a statistical character.

Nevertheless, much valuable information is contained in the archives of insurance companies, and all analyses of the available material are welcome.

Treatment in General Practice: Surgery. Articles republished from the *British Medical Journal*. Vol. IV. 8°, cloth, 562 pp., with 143 illustrations. London: H. K. Lewis and Company, Limited, 1940. 16s net.

The *British Medical Journal* has published a number of articles on treatment, part of which are incorporated in this fourth volume of a series. It deals with surgery in general practice and reviews the latest treatment in some of the commoner surgical affections. A large section of this book is devoted to fractures and traumatic surgery. There are other chapters on such varied subjects as pruritus ani and prostatectomy.

The principal features of this book are a simplicity and clarity of presentation and a minimum of detail. It is designed to instruct the busy practitioner who can read only a chapter or a paragraph between patients. The material offers nothing startling or new in therapy, but is more in the nature of a review of accepted practice.

For the American practitioner, some of the specific remedies will be difficult to understand, because of the proprietary names used in their designation.

Diagnosis and Treatment of Arthritis and Allied Disorders. By H. M. Margolis, M.D. 8°, cloth, 551 pp., with 140 illustrations. New York: Paul B. Hoeber, Incorporated, 1940. \$7.50.

This volume, written primarily for the family physician, attempts to present, in a concise manner, present-day knowledge of rheumatic diseases. The author has accomplished this as well as had been done in any volume on arthritis yet published. The arrangement is logical, and the pictures are good and well chosen. For

those who wish a fuller discussion, there is an adequate list of references. The book is well written.

It is unfortunate, however, that the men who write about arthritis consider it necessary to discuss all the related conditions that appear in the joints. In this book, two fifths of the pages are taken up with a discussion of orthopedic conditions that should have been left to treatises on orthopedic surgery. The book should be a helpful one for the busy family physician who is called on particularly for the early treatment of patients suffering from rheumatic diseases.

The Endocrine Glands. By Max A. Goldzieher, M.D. 8°, cloth, 916 pp., with 271 illustrations. New York: D. Appleton-Century Company, Incorporated, 1939. \$10.00.

For one person to write a textbook of endocrinology is to attempt what is almost impossible; the author has made this attempt, but rather unsuccessfully, according to the opinion of the reviewer. Side by side with much material that has been handed down from one textbook to another appear quite up-to-date conceptions of the pathogenesis of certain disorders; it is too bad that many concepts which have not been scientifically substantiated through the passage of years have been allowed to remain. Very often cases referred to in the text are found on careful study not to illustrate the citation. With all these criticisms, it must be said that the prefacing paragraphs on embryology and physiology of the gland under discussion are excellent; in the bibliography, there seems to be an excellent introduction to the German literature, with which the author is undoubtedly very familiar.

Vitamin Therapy in General Practice. By Edgar S. Gordon, M.D., and Elmer L. Sevringhaus, M.D. 8°, cloth, 258 pp., with 35 illustrations. Chicago: Year Book Publishers, Incorporated, 1940. \$3.25.

This book presents to the clinician in a concise manner the information he needs to understand nutritional requirements and deficiencies. The vitamins are presented as a specific chemical compound playing particular roles in cellular physiology. The reader will realize that vitamins no longer are mysterious, unknown substances that can be measured only in terms of some arbitrary unit related to their biologic activity in some convenient experimental animal. As known chemical compounds, their requirements and therapeutic doses may now be designated simply in terms of milligrams. The clinician should be the first to welcome and utilize this simplification, which has been made possible by advancing knowledge.

The chapters on minerals, proteins, carbohydrates and fats present much that will refresh and supplement the clinician's knowledge. The discussion concerning low-carbohydrate versus high-carbohydrate diets in diabetes mellitus is both sound and needed. The chapter on weight control places the desired emphasis on dietary factors and control at a time when endocrine factors and therapy are so often stressed.

One regrets that the high standard of up-to-date knowledge set throughout most of the book is injured by such statements as: that a plasma ascorbic acid concentration of "from 1.0 to 0.5 mg. per cent may be considered as borderline and below 0.5 mg. a definite deficiency may be assumed to exist"; or that calcium lactate and gluconate are better sources of bone and tooth salts than calcium phosphate. And one regrets also that the high standard of accurate information is marred by an unsubstantiated

claim concerning the efficacy of vitamin P in purpura and by the statements that the characteristic laboratory finding during active rickets is primarily a fall in 'blood calcium level' and that the phosphorus in the blood also falls, but usually does not go below 25 to 30 mg per cent.

In spite of these rare flaws, the reader will both enjoy and profit by reading this book. And, if in reading the last chapter he is shaken from his complacent belief that this nation is well fed, his reading may be of much benefit to many.

A Pioneer Doctor in Old Japan The story of John C. Berry M.D. By Katherine Fiske Berry 8°, cloth, 247 pp., with 20 illustrations. New York: Fleming H. Revell Company, 1940. \$2.50.

Dr. Berry was born in Maine, on the Kennebec River in 1847. He studied medicine at Bowdoin College and took an eighteen month internship at the United States Marine Hospital in Portland. He then entered the Jefferson Medical College in Philadelphia, where he graduated with honor in 1871. After a few months of practice, he went to Japan with a mission for the American Board of Foreign Missions of Boston. He crossed the Pacific in a side wheeler, with the girl he had recently married, and started to work in Kobe, as a successor to another American physician, Dr. James C. Hepburn who had written the first Japanese English dictionary.

This book tells of Dr. Berry's long service in Japan. The latter part of his life was spent in Worcester, where he practiced as an otolaryngologist, until his eighty-eighth year. This charming biography is written by his daughter. In it will be found an exceptional picture of Japan and the splendid medical work done by missionaries such as Dr. Berry. Japan will not soon forget the life of this extraordinary person, and Americans may well be proud of a compatriot who did so much for a foreign country.

History of Pharmacy A guide and a survey By Edward Kremers, Ph.D., Ph.M., Ph.D., Sc.D., and George Urdang, Ph.D. D.Sc. Nat. 8°, cloth, 466 pp., with 30 illustrations. Philadelphia: J. B. Lippincott Company, 1940. \$4.50.

The work is divided into three parts, the third of which, having to do with pharmacy in the United States, is the first comprehensive treatment of that particular period in pharmacy. The first two parts, comprising 108 pages, deal with the early history of pharmacy and the rise of professional pharmacy in the various countries of Europe.

The book is written from the viewpoint of teaching, and for this reason the work has been kept within a comparatively small number of pages. The various supplements add to the value of the book, and the bibliography of thirty pages documents the authors' statements.

Modern Drug Encyclopedia and Therapeutic Guide By Jacob Gutman, M.D. Ph.D. Second edition 8°, cloth 1644 pp. New York: New Modern Drugs, 1941. \$7.00.

This encyclopedia is arranged on the same plan as the *Pharmacopoeia of the United States*. It presents the descriptions of 11,114 modern ethical medicinal preparations in 15,629 forms, all of which are not in the *pharmacopoeia*. It has two comprehensive indices, one of drugs and general matters and the other a therapeutic index.

This book should be valuable to those concerned with proprietary drugs and medicinal preparations.

Progress in Medicine A critical review of the last hundred years By Igo Galdston, M.D. With a foreword by Henry E. Sigerist, M.D. 8°, cloth, 361 pp. New York: Alfred A. Knopf, 1940. \$3.00.

The author offers to students of science and the history of medicine an instructive and challenging account of the last hundred years of progress in medicine. It should be noted that he not only presents conclusions that have crystallized out of the controversies of other times, but also gives careful consideration to living issues. After carefully reading this book, students will come to see that many facts that the labors of earlier generations brought to light were at best provisional, and that this historical lesson is vitally applicable in modern times. The discussion is presented in clear, terse style and with a scholarly regard to historical perspective. A chapter, 'The Genius of Pasteur', is preceded by 'The Preludes to Pasteur' and followed by 'The Pasteurians'. Then follow chapters entitled 'The Reign of the Microbes', 'The Challenge of Nutrition', 'The Inner Realm and the Endocrines', 'From Mesmer to Freud', 'Freud and Modern Psychiatry', 'A Century of Clinical Progress' and 'Whither Medicine?'. This adroitly handled account of medicine during the last hundred years is strongly recommended for careful study to undergraduates and to graduates in science.

Complete Guide for the Deafened By A. F. Niemoeller, A.B. M.A., B.S. With a foreword by Harold Hays, M.D. 8°, cloth, 156 pp. New York: Harvest House, 1940. \$3.00.

This book is well written and in a language that the lay person can understand. It describes the causes of deafness and the relation of various diseases to deafness. It also discusses the effects of explosive sounds and operations of the ear on hearing. There are good sections on hearing tests, the use of the audiometer and the methods of retraining the deaf. The book should be of great value to the otologist, since it gives the viewpoint of the deafened person and also outlines the proper psychological approach to be used with the deaf person.

Foreign Bodies Left in the Abdomen The surgical problems cases treatment, prevention The legal problems cases decisions, responsibilities By Harry Sturgeon Crossen, M.D., and David Frederic Crossen, LL.B. 4°, cloth, 762 pp., with 212 illustrations, including 4 color plates. St. Louis: The C. V. Mosby Company, 1940. \$10.00.

The authors have put a great deal of painstaking effort into the writing of this book. It is a medicolegal exposition on the problems of foreign bodies left in the body at the time of operation, and is written by a surgeon and a lawyer. It is more in the nature of an encyclopedia and reference book for the use of a person with such a problem in hand. The great detail of the case reports and of the individual experiences precludes a cover-to-cover reading simply for interest in the material presented.

The most valuable part of the volume to the practicing surgeon is that which considers prevention of these unfortunate accidents. Use of the continuous-strip instead of individual sponges is advocated as the safest method for packing away the abdominal contents. A chapter on ingested foreign bodies is interesting because it again calls attention to the amazing array of objects that the alimentary canal can expel spontaneously.

This book will find its greatest usefulness in the reference library for those who are called on to assist in the legal solution of these cases.

A Surgeon Explains to the Layman. By M. Benmosché, M.D. 8°, cloth, 317 pp., with 62 illustrations. New York: Simon and Schuster, 1940. \$3.00.

In this book the author has attempted to popularize the commoner surgical procedures. To the reviewer, it seems that the type of person who will read such a volume for self-education is the one who is intelligent enough to consult his physician for unexplained symptoms. In such cases, the physician can describe a specific disease for the patient better than any book. Other classes of patients are better reached through magazines, cinema and radio than through such a medium as this. They are the ones who will at best understand and follow such a simple rule as, "Don't take a laxative for pain in the abdomen; see a doctor first."

The reviewer believes that the author has made an effort to popularize a subject that does not lend itself well to such a purpose.

The 1940 Year Book for Industrial and Orthopedic Surgery. Edited by Charles F. Painter, M.D. 12°, cloth, 484 pp., with 299 illustrations. Chicago: The Year Book Publishers, Incorporated. 1940. \$3.00.

In this small book, the author has attempted to condense the worthwhile contributions in orthopedic surgery of the past year, and he has succeeded as well as possible with so large a task. The book is clearly and concisely written. The arrangement is commendable, and the subject matter is well outlined and indexed.

Unfortunately, what constitutes a contribution to orthopedic surgery and what amount of emphasis each topic should be given are matters on which each orthopedic surgeon differs. Tuberculosis receives more attention than its present-day importance seems to merit, and congenital and developmental deformities are given very brief notice. The section on fractures is one of the best in the book. The same thing might be said of the final chapter on industrial medicine.

The style is good, a rare thing in medical treatises of this generation. The book is interesting reading. It is an excellent compendium of present-day orthopedic practice and should prove helpful to all orthopedic and industrial surgeons.

Psychotherapy: Treatment that attempts to improve the condition of a human being by means of influences that are brought to bear upon his mind. By Lewellys F. Barker, M.D. 12°, cloth, 218 pp. New York: D. Appleton-Century Company, Incorporated, 1940. \$2.00.

Few men in America are so well qualified by virtue of wide medical experience to discuss psychotherapy as Dr. Barker. This book is ample proof that he has dealt with patients in various stages of mental disturbance for a long and profitable period.

Dr. Barker points out, soon after defining his understanding of the title, the importance of making comprehensive diagnostic studies on which adequate treatment can be based. He believes that a knowledge of the heredity and environment of a patient is of extreme importance in mapping a plan of specific treatment. The methods of mental therapy, such as suggestion and hypnosis, persuasion, rest and isolation, are capably reviewed before he discusses the more comprehensive treatments associated with the name of a single psychiatrist.

Psychoanalysis is considered not only as a psychological entity and technic but also as a historical landmark. The dependence of the "psychological analysis" of Janet, the "individual psychology" of Adler and the "analytical psychology" of Jung on the basic technic is extensively elaborated. The contributions of Stekel and Rank are reviewed.

Psychotherapy in the various ages of life (childhood, adolescence, adulthood, in later life and old age) forms a large part of the volume, but psychotherapy as it relates to the treatment of organic and functional disorders is not neglected. A chapter on the future of psychotherapy is inspiring and should be read by those physicians who believe that psychological treatment has reached a cul-de-sac beyond which no further application can be envisioned.

This book warrants the attention of physicians who do not specialize in psychiatry, and of medical students, social workers and persons who wish to obtain a broad view of the field or who wish a starting point for more intensive studies.

Fractures and Dislocations for Practitioners. By Edwin O. Geckeler, M.D. Second edition. 8°, cloth, 314 pp., with 267 illustrations. Baltimore: Williams and Wilkins Company, 1940. \$4.00.

The first edition of this book, published in 1937, had of necessity to be soon followed by a second, because so rapid a pace is being set by those who are interested in the treatment of injuries to bones. It is clearly written, well illustrated and full of practical suggestions concerning methods of treatment. The emphasis laid on after-care should be taken to heart, for more depends on it than some recognize. The modern operative approach to such cases as are better handled by open methods is well defined, and the technic is outlined.

This volume can be enthusiastically recommended to all who wish a concise statement of the essentials of the treatment of fractures and dislocations.

Taber's Cyclopedic Medical Dictionary. By Clarence Wilbur Taber. 12°, cloth, 1372 pp., with 273 illustrations. Philadelphia: F. A. Davis Company, 1940. \$2.50.

This small dictionary of 50,000 words is a new publication in the field of dictionaries and is not a revision of the author's digest of medical terms, which was published in 1937.

Of particular interest are the appendices, consisting of a glossary of Latin medical words, definitions of prefixes and suffixes and "the interpreter," which is a phrase book written in five languages and especially arranged for diagnosis.

Dizionario di medicina per medici e famiglie. By Dott. Giulio Casalini. F°, cloth. Vol. 1, 868 pp., with 1550 illustrations and 24 color plates; Vol. 2, 917 pp., with 1912 illustrations and 35 color plates. Torino, Italy: Corso Taffiello, 1939. Lire 300.

This well-illustrated dictionary is encyclopedic in character. There are 8000 subjects, ranging in size from a few lines to a number of pages, and illustrated with many figures and plates, some of which are in color.

The work is well printed on good paper and reflects the current aspect of Italian medicine. The dictionary was written for both physicians and the laity, and Dr. Casalini was assisted by a corps of twelve eminent Italian professors and doctors.

THE CARE OF THE HOSPITAL OUTPATIENT*

T. GRIER MILLER, M.D.

PHILADELPHIA

I AM deeply appreciative of the honor that has been conferred on me by the opportunity to present this George Washington Gay Lecture on the Care of the Patient. I have accepted the invitation of your committee in a corresponding spirit of humility and with a full realization of my inability to contribute anything of importance to the masterful addresses on the art of individual medical practice already delivered in this series by Peabody, Thayer, Herrick and other distinguished clinicians. Their presentations were of such a fundamental nature and on such a broad human basis that they will stand permanently as guides in the art of medicine. Fortunately, however, Dr. Gay, being a person of wisdom and foresight, established his foundation for lectures on the economics as well as the ethics of medicine, and therefore undoubtedly anticipated a need for constant change in the organization of the profession for the provision of efficient and at the same time reasonably priced medical service. In any event, I am taking advantage of such an interpretation of his conception of the future of medicine to discuss some of the more recent developments in the care of the patient, especially with reference to its accomplishment by a group of practitioners rather than by an individual physician. This type of practice for the hospital inpatient has for a long time been well established, and, by referring more specifically to its employment in the care of the hospital outpatient, I wish to indicate its equal availability and some of the advantages of its more general use in other fields of medical endeavor.

No matter what form of practice may ultimately develop, however, let us not forget that the care of the individual patient always constitutes the primary function of the physician and that this implies more than the management of the disease from which the person suffers. Since the develop-

ment of disease depends on the reactions of a person to unfavorable conditions in life, its control, including its prevention, may involve not only a consideration of each patient's innate constitution, of his physical, mental and emotional equipment, of his personality, of his habits, of his social relations and of his contacts with the physical world, but also an appraisal of all the factors, internal and external, that tend to create for him an abnormal situation. Thus, whether it grows out of the science or the art of medicine or comes from some of the related sciences or arts, every recorded observation, every established fact, every technic and every human effort that contributes to the prevention, recognition or management of a diseased state in man may be regarded as in keeping with the fundamental aim of medicine.

The accomplishment of good care for the patient, therefore, requires not only a knowledge of disease itself and of the technics for its prevention and amelioration, but also an understanding of the person who has the disease and the skill with which to apply the effective therapeutic procedures. The established facts regarding disease and its treatment may be acquired from the observation of others, and it may be assumed that you, as Harvard students, have already learned many of these from your teachers, your textbooks and the current medical journals, but to understand people and to have the skill with which to apply your knowledge to the alleviation of their ills is a far more difficult matter and is never completely mastered.

The changes in the methods of practice that are now taking place have been attributed by some to a desire on the part of the Government to socialize every phase of life, to regiment all our activities and to limit our personal freedom, but, for medicine at least, the modern viewpoint can be explained on a far simpler and more rational basis. Not so long ago the family physician was presumably instructed in all the currently known

*A George W. Gay Lecture on the Care of the Patient delivered before the students of the Harvard Medical School January 9, 1941. From the Gastro-Intestinal Section (Kinsey-Thomas Foundation) of the Medical Clinic University of Pennsylvania Hospital.

Professor of Clinical Medicine University of Pennsylvania School of Medicine

aspects of medicine; his patients were usually his neighbors and his intimate friends, he knew their heredity and their personal habits, and he was supposed to know, under most circumstances, what the profession had to offer for the relief of their ailments. Furthermore, when a particularly difficult clinical situation, diagnostic or therapeutic, arose he could only call in a colleague or consultant whose advice was based largely on personal experience with similar cases. No exact methods of diagnosis and no specific therapeutic procedures were available. With the development of surgery, and later of the specialties, with the great advances in the scientific knowledge of disease and especially with the development of the modern hospital, including its special facilities for diagnosis and treatment, it obviously became impossible for any one physician, no matter how well trained and equipped, to meet all the needs of some of his patients. Consultants, furthermore, instead of making a diagnosis or advising therapy on purely clinical observation of the case or on their general experience, began to demand exact scientific data, and patients themselves began to question the diagnosis and the forms of treatment that were not based on exact laboratory procedures.

It is readily admitted that in the great majority of cases the disease can be easily and satisfactorily diagnosed and managed by a competent practitioner. In fact, not only because it involves less time and expense but also for psychologic reasons, complete care by a single physician is often more effective. No system of practice, as a matter of fact, that requires useless professional activity or unnecessary procedures of any kind will serve the patient's or the public's best interest. And yet the problems of some patients are so complicated and the available means for attacking them are now so specialized that a group of physicians, many of them differently trained and equipped, must be called on to deal with the individual case. Their efforts, however, to be maximally effective must always be directed and co-ordinated by some single person, the personal adviser at least for the time being, so as to afford the patient a consistent program of intelligent care.

The importance of having at all times for each patient, no matter what the nature of his case, a competent physician responsible either for all the care that is demanded or at least for its administration by others is generally appreciated. Yet, in the process of the change that is now taking place in medical procedure, many patients have lost the kindly, continued medical supervision that constituted the chief advantage of the older system. Even in the wards of our hos-

pitals, where all the physicians concerned are closely associated, it sometimes happens that no one of them becomes the patient's personal adviser, co-ordinates the efforts that are made in his behalf and sees to it that his emotional as well as his physical problems receive their due share of attention. About this aspect of the matter Peabody spoke most emphatically in his Gay Lecture of 1927; it demands equal emphasis today. In private practice, except perhaps with the financially well-to-do, the situation is even more serious: because of the added expense or for fear of losing the patient, the practitioner may not seek the advice of qualified specialists, or, if he does so, may not be in a position to control the further management of the case. On the other hand, the specialists involved, because of a lack of personal contact with the referring physician or with each other, may be in ignorance of important aspects of the case other than their own. Finally, the patient himself, irrespective of his financial status, may choose his own specialist, often incorrectly, or may drift from one physician to another with no correlated supervision. In the end, he may put himself in the hands of a cultist or give up in despair.

At any rate, in spite of the improvement in medical facilities, the great mass of the population is not yet receiving the good medical care that the profession is capable of supplying. Statistics concerning the supply and distribution of physicians and the number of people within or beyond their reach in the country at large vary greatly, but are of little, if any, value, since they do not indicate the type of care that is available. The unfortunate situation is better shown by the number of patients who come to hospitals, even in the large cities, with an unrecognized and hopeless cancerous lesion, with a neglected and advanced pulmonary tuberculosis, with a ruptured appendix, with a long-standing intestinal obstruction or with a severe but preventable type of infection. Too often one finds that the family physician had failed to do a digital examination of the rectum, to palpate a breast, to make a careful clinical study of the chest or to do a blood count or a simple urinalysis. I do not want to be unfair to our profession, but we must face the situation, and admit either that many of our general practitioners are incompetent to render good medical care or that the present system of practice does not permit them to render the service of which they are capable.

One cannot entirely excuse the average practitioner for such a situation, or fail to take advantage of the opportunity to urge better training for him: and yet, before we place the chief blame on the

family physician, let us remember that far more is expected of him than in the past, that he too, to an extent, may be a specialist of some sort, that his small fees limit greatly his time for the individual patient, and that once in active practice, he often has little opportunity to keep abreast of the advances in medicine.

The hope for better care of the average patient, therefore, seems to lie largely in some reorganization of the system of practice, one that would make available to the practitioner all the facilities needed for the care of his patient and at the same time permit the physician to make a good living and to do his work leisurely and effectively.

Special types of highly organized medicine have developed in response to this situation: the elaborate medical departments of the United States Army and Navy, to meet the health needs of our active soldiers and sailors; the veterans' hospitals, to care for the physical handicaps of previously enlisted men; institutions, under governmental auspices, for the supervision of the insane and the tuberculous; industrial medical units, for the care of employees and sometimes of their families; finally, various associations of physicians for the conduct of private practice, sometimes under an insurance system.

Before discussing the hospital outpatient department as a further example of this type of practice, and one that is organized to function in cooperation with the general practitioner, it is worth while to consider the essentials of good medical care. I think they may be summarized as accurate diagnosis, the economical and efficient employment of all the established measures of therapy, and continuous personal supervision of the patient as an individual.

Surely accurate diagnosis is the first requirement. This involves, in many cases, much more than the securing of a detailed story of the patient's symptoms, of his past medical experiences and of his family and social relations; it includes more than a meticulous physical examination and the accomplishment of a few routine laboratory tests. Frequently it necessitates, at least for purposes of elimination, the services of specially trained professional and technical workers: chemists, bacteriologists, roentgenologists, ophthalmologists, urologists, gynecologists, otolaryngologists and, sometimes, general surgeons. It requires, furthermore, that the results of the studies of these specialists be assembled and analyzed, in the light of the primary clinical observations, by someone who is highly trained and experienced in the broader aspects of clinical medicine, by one who stands in the position of "physician" to the particular patient.

The second essential for good medical care is that all the necessary facilities for the treatment of the diagnosed condition be made available to the patient. This may involve nothing more than an assurance on the part of the original physician that no disease process has been discovered, and some advice about the patient's manner of living or the regulation of his diet; but it may require the services of another special group of professional and technical workers, such as surgeons, roentgenologists, psychiatrists and physiotherapists. It may necessitate the employment of elaborate physical equipment: a roentgen-ray machine, orthopedic apparatus, gymnasiums and so forth. It may, of course, demand hospitalization of the patient.

The third and equally important requirement is continuous personal supervision of the patient throughout the period of his study and of his treatment. On the success or failure of this phase of care, which involves primarily the art of medicine, rest to a large extent the degree of cooperation of the patient and the ultimate result of the therapeutic effort. So far as possible, the doctor originally consulted by the patient should assume the responsibility for his total management. In most cases he will be the family physician, the general practitioner or the internist, but whatever his type of work, if he is capable of carrying through this aspect of the patient's care, he may be regarded as a "physician." Although I fortunately have the privilege of knowing many specialists and surgeons who are excellent physicians, I know others, even internists, who function largely as specialists, in the narrow sense of that term, having no interest in the patient beyond the management of his disease, and in that only so far as it fits into their special fields of scientific effort. Such a person, no matter what his qualifications in a special line of work, cannot be looked on in the true sense of the word as a physician. Such a specialist, to supply all the essentials of medical care to his patient, must usually function in cooperation with another practitioner, one who can assume responsibility for the general management of the patient, one who will be his "physician."

Sometimes, for special diagnostic investigations, for therapy, for personal reasons of the patient or the doctor or for a new viewpoint regarding the case, it is necessary at least temporarily to transfer the patient from the supervision of one physician to that of another, as, for example, when hospitalization is required, when the immediate disease process lies outside the range of the first doctor's activity or when an assigned professional service in a clinic or hospital terminates. Under such cir-

cumstances the transfer of responsibility should be clearly understood by the patient as well as by the recipient physician. Only in this way can a continuity of personal supervisory service to the patient be maintained and his thorough cooperation secured. Furthermore, when the situation is so managed and the activities of the second physician have been completed, the patient ordinarily should return to his former physician and thereby maintain a more permanent relation with him. Such an arrangement not only makes for consistent care of the patient but at the same time establishes and maintains a cordial relation among physicians.

I shall now discuss the hospital outpatient and consider to what extent the organization that has been developed for his care meets the indications that I have outlined, and incidentally to what extent it has failed to do so.

From one point of view, at least, the outpatient has from the start a great advantage over the ordinary private patient: like the ward patient, he does not have to pay the costs of his medical care. He may be admitted to the hospital clinic on an entirely free basis, or, if able, he may pay something to the institution, but under no circumstances are the services limited by his economic status, and there is no financial relation between the doctor and the patient. This divorce of the monetary aspects of the care of the patient from its professional phases is significant not only for the patient, but also for the physician. It frees the former from the fear of jeopardizing his economic status, whatever it may be, or of incurring financial obligations that he cannot meet; it gives the latter free rein to devote to the patient and to demand of him whatever amount of time the case deserves, to seek such laboratory and professional aid as may be needed for diagnosis or treatment, and to establish a personal relation unhampered by any thought, on his part or that of the patient, of subsequent materialistic adjustment. Under such circumstances the professional and personal aspects of the doctor-patient relation take precedence over all others and create an ideal background for good medical care.

In this connection, it may be appropriate to say a word regarding the free choice of physician, about which there has recently arisen a great deal of controversy. The hospital outpatient has no opportunity to select his physician although in many institutions if he is dissatisfied with the one to whom he has been assigned he may, on request, be transferred to someone else in the same department. In my experience such a request has rarely been made. The average patient comes or is sent by his family doctor to an institution because of its

reputation in the community, and, so long as he is receiving what I have defined as good medical care, he is co-operative, quickly develops a sense of loyalty to his physician and expects no variations from the routine of the organization except as indicated by his professional needs. It is to be assumed, however, that at each visit for a reasonable period the patient sees the same physician, as he would if consulting a private practitioner, and that, in consequence, no confusion about the continuous personal management of his case develops.

Since I have defined accurate diagnosis as the first essential in good medical care, I shall now review the opportunities for exhaustive study of the patient in the outpatient department of a general hospital. The entire facilities of the hospital, so far as they can be utilized for an ambulatory patient, may be made available. This includes not only the physical apparatus, such as the roentgen-ray equipment and the laboratories, but also the entire personnel of the hospital, professional and technical. From the viewpoint of the hospital's service to its community, the outpatient department may become, perhaps is already, of even greater importance than the ward. A larger number of patients can be cared for, in most instances they are in the earlier stages of their disease and they can oftener be cured and again made useful citizens. In addition, many of the patients, except for the outpatient service, would eventually become ward cases and so require the additional expense incident to lodging and board. Furthermore, many outpatients, even while under observation, may continue their employment, and consequently at the same time be productive citizens, supporting themselves and their families. It behooves the hospital, therefore, as a public institution, to contribute to outpatients all its available resources for diagnosis and for treatment.

In some institutions only the younger and less seasoned clinicians do the outpatient work, but from the viewpoint of their service to the community the more experienced staff members, if only in an administrative or consultant capacity, might be of greater value in the dispensary than they are in the ward.

In any event, a well-organized outpatient department, co-operating freely with similar units in a general hospital and having the entire physical and personnel facilities of the institution at its disposal, is ideally equipped to afford accurate diagnosis for its patients.

As to the second essential for good medical care, that of treatment, little more need be said. If the facilities for diagnosis are available, so also

are those for treatment. This may sometimes involve the necessity for hospitalization, but it is astonishing to what extent the development of efficient outpatient departments, in addition to the advance in methods of therapy, has diminished the reference of certain patients to hospital wards. In my intern days, our wards were filled with patients of a type that are now equally or better cared for on an ambulatory basis, especially those with pernicious anemia, diabetes, peptic ulcer and gall-bladder disease, and some with cardiac, renal and pulmonary disease. Now such patients rarely need be admitted to a hospital for diagnosis, and for treatment only when the disease is well advanced or refractory or demands prolonged bed rest or surgery. From a gastrointestinal clinic I find that, although we still refer many patients to the surgical wards, only rarely is it necessary to hospitalize them for diagnosis or even for medical treatment.

The chief difficulty in the outpatient department concerns the third essential for good medical care: continuous personal supervision of the patient. This, however, is because we have not always given proper consideration to the art of medicine in our outpatient services. Owing to the number of patients, the relatively brief period available for each one, the physician's desire to see as many of them as possible, his primary interest in the abnormalities that they present or a feeling that they are "only outpatients," the human side of their problems has been neglected. Sometimes perhaps we have been too ready to pass them on to some other department for a tonsillectomy, a tooth extraction, a gynecologic examination or some other diagnostic study, or for some form of treatment by a specialist. There the patient's association with the hospital may have ended, or he may have been sent on to another clinic, no one taking the trouble to act as his "physician."

Outpatients, however, are just as human as private ones, and although usually more easily controlled, they require an equal consideration of their personal problems. Often they go to the hospital after considerable hesitation about doing so, but they usually go because they want help, and they are keenly appreciative of any manifestation of interest and sympathy. The greater the intellectual gap between them and their physician the easier it is to establish an emotional relation: one of friendship, of loyalty, of understanding and of an obvious desire to help. To such an attitude on the part of the physician, the average outpatient readily responds with the utmost co-operation. Furthermore, it rarely requires any extra time to

develop such a personal relation, for it is largely a matter of the physician's manner and of his consideration of the patient's personal as well as of his specific medical problems. The interest must be maintained, however, and must extend to the patient's management so long as he is under the physician's observation.

Some such relation with the patient should also be manifested by all those with whom he is associated. The admission clerk, the secretary, the nurse, the social-service worker, the laboratory technician, as well as the physician, should constantly maintain toward him an attitude of friendliness and of personal concern for his welfare. Any one of these, by an injudicious remark, a display of temper, an indication of prejudice, a sign of preference for one patient over another or an unkind act of any sort, may so disturb the patient as to undo the best efforts on the part of the others. On the other hand, some one of the group—oftenest a secretary, a nurse, a social-service worker or an officially designated hostess—may so impress the patient with her interest in his case and her personal desire to help him, that she may greatly simplify the duties of the physician in this regard. Ideally, if a person with such qualifications is available on the staff of a clinic, her other duties should be subordinated to this most important one. She should welcome the patient to the department, even before he meets his clinic physician, should see him again before he leaves and should discuss with him subsequent visits, detailed arrangements for consultations with other physicians of the hospital, for laboratory procedures and for hospitalization. She should also be the one to accompany him to other departments of the hospital, to visit him in the wards and often to lend moral support when an important decision—for example, regarding an operation—is to be made. In some cases she should be with him when he goes to the operating room. In such a way a single member of the staff, not necessarily and perhaps preferably not a physician, may give continuity to a patient's care and at the same time greatly relieve the professional staff.

Finally it becomes necessary to consider the ultimate disposition of the outpatient. If he has been referred by a family physician, whether merely for diagnosis or for diagnosis and treatment, the matter is not difficult. When the diagnostic studies have been completed or the indicated treatment has been given, the patient is referred back to that physician and the latter is informed, preferably in writing, of what has been accomplished. The patient is then again in the hands of his original physician, and presumably he will continue to

consult him from time to time as the occasion demands.

For the unreferral patient, however, who is usually indigent, the matter is more difficult. The hospital's duty to him is not ended until his disease is cured, or at least until his physical condition is stationary and requires no further professional observation. If he develops a subsequent illness that demands only ambulatory supervision, he will presumably return to the same hospital for reference to the proper clinic. If, however, he develops a disease that requires home care, few clinics or dispensaries are able to handle the situation. Boston, however, is fortunate in this respect, having the Boston Dispensary, the obstetric service of the Boston Lying-in Hospital and the pediatric service of the Boston Floating Hospital, all of which supply home care. Ordinarily the former outpatient, when a new illness develops and he cannot return to the clinic, calls in a local physician, whether or not he is able to pay for such special service, or he goes without medical supervision. When the physician knows that he cannot be paid, which happens with most former outpatients, it is unfair to expect him always to render what I have defined as good care; when the patient does not seek medical advice, he may not only endanger his own life but also become a menace to his family and his community. The care of the indigent is not, therefore, as yet completely solved, even by most hospital outpatient departments.

Thus even in the large cities, where the hospitals are well staffed and equipped and the outpatient services are well organized, some of the problems of the patient who cannot afford to pay for medical attention remain unsolved. How much more acute must this problem be in the small cities and the rural communities, in some of which no hospital exists, or at least none with provisions for the complete study and treatment of the ambulatory patient. His medical care, under such circumstances, depends not on the community at large but on the charity of the local medical profession.

One is led, therefore, on the basis of these considerations of hospital outpatient service, to speculate on the extent to which the principles that I have discussed may be applied to the supervision of the private patient of moderate means. He does not expect, nor is it desirable from his or a public viewpoint, that his medical services should be secured on a charity basis, and yet it is highly important that he have the opportunity to secure at least as good care as the hospital outpatient. This implies that all the facilities for an accurate diagnosis, for comprehensive treatment and for continuous personal supervision by a physician be

made available to him. The chief difficulty is an economic one. Its solution seems to lie in some plan by which the cost can be kept within his means. Various experiments along this line have been developed: formally organized clinics, including a hospital, such as that of the Mayos, in which the cost is carefully adjusted to the patient's ability to pay; pay and part-pay clinics, such as those of some of our large general hospitals, to which patients of a limited income are admitted; specially constituted groups of private physicians, largely for office practice, such as have developed in our western states; and less formally organized groups of physicians, such as the Boston White Cross, in which each physician functions independently, except that the usual fees are replaced by payments from a pooled income, which is derived from periodic and special-service contributions by the subscribing members. Although in the past the individual doctor cared for all the patients in his community, irrespective of their ability to pay, and evened up his income by good fees from the more affluent, the present tendency is to charge each enrolled person the same fee, irrespective of the amount of service required. Any of these systems leads to a controlled distribution among the physicians of the total professional income, but perhaps to a more equitable distribution, because it may be based on merit and the type of service rendered. Such an arrangement should prove especially attractive to the well-trained younger men in the profession, because they are in great demand by such groups and because from the beginning they can be assured of a reasonable income, of an association with older and more experienced practitioners and of more regular hours of work.

In spite, however, of the obvious advantages of group practice for those of moderate means or even of the wealthier classes, it must constantly be remembered that in at least one important respect it differs from hospital outpatient service: its financial aspect. The members of a hospital staff are on a salary or give their services without remuneration. Whatever compensation they may obtain bears no relation to the number or kind of patients cared for or to the type of service rendered. On the other hand, in the private group, large amounts of money are often handled, its distribution is determined more or less arbitrarily, opportunities for unfairness and discrimination arise, and personal jealousies among the participants not infrequently develop. I do not wish to discuss this phase of private group practice, but merely to call attention, in connection with it, to the importance of honest and open financial arrangements that will prevent unfair practices,

such as fee-splitting, the unnecessary use of professional and technical facilities and questionable advertising.

Any such plan for the care of the patient of moderate means by a group of physicians and on a prearranged cost basis need not, however, interfere with a continuance of private practice, as now understood, so long as the other more favorable features of group care are in some way maintained. Many of the patients with an easily diagnosed and simply treated disease can, of course, be adequately managed by the practitioner functioning alone, but unless he has intimate association with a variety of physicians whose training and skills are along lines other than his own, unless ample technical assistance and physical equipment are available either to him or to his associates and unless he has the free time to take advantage of opportunities for reading and for study of the new developments in medicine, he is likely to fail in the provision of the best possible service for his other and more difficult cases. Evidence of an appreciation of the importance in private practice of such professional associations, such mechanical aids in diagnosis and treatment and such continued education is now apparent in the

tendency of the physician to seek offices in a hospital or professional building, where these associations and physical facilities are available, in his interest in postgraduate courses of study and in the rapidly mounting membership of our national societies.

Finally let me emphasize, however, that, no matter what the organization for the practice of medicine, its ultimate success depends on the training, the skill, the intelligence and the character of the individual physician and especially on his capacity to render sympathetic, continuous and personal service to the individual patient.

Many other interesting aspects of the care of the patient readily present themselves, but my purpose today has been merely to arouse your interest in some of the broader problems and to indicate to what extent the present practice in the outpatient departments of our hospitals has already shown a solution of them. I trust that it may lead some of you to a determination not only to be proficient in the science and the art of medicine but also to strive to perfect for the public better facilities for good medical care.

3600 Spruce Street

* PAIN IN CANCER OF THE FACE, JAWS AND NECK*

An End-Result Study of the Relief Afforded by Neurosurgical Methods

DONALD MUNRO, M.D.†

BOSTON

IT HAS been generally believed that pain associated with cancer of the face, jaws and neck can be permanently relieved by some neurosurgical procedure whenever the patient and the doctor make up their minds to have it carried out. Furthermore, except by those who are familiar with the intimate details of cancer therapy, it is also widely assumed that the pain associated with cancer in these locations is traceable to the disease and not to the methods used in treating it. Based on these assumptions, operations that denervate the diseased areas have always been held in reserve until the last possible moment. This report of an end-result study of 30 cases of cancer demonstrates the inaccuracy of both hypotheses. Superficially the findings are most discouraging, but they emphasize, nevertheless, certain fundamental truths that can be expected to point the way in the future to not only greater comfort for these

patients but also to the promise of greater efficiency in cancer therapy.

All these patients were referred to me for relief of pain. Except so far as it was required by such emergencies as a sudden hemorrhage, the therapy, while the patients were under my care, was directed toward that end alone. Fourteen cases came from the Collis P. Huntington Memorial Hospital. Four patients died while under treatment. One of these was not operated on but developed a fatal inhalation pneumonia in two weeks; another died from peripheral circulatory collapse associated with tuberculosis and cancer of the cervical lymph nodes and cancer of the lung and mediastinum; the third died because of cachexia and carcinomatosis; and the fourth death followed a ligation of the carotid artery for hemorrhage. Although all the others were asked to do so, only 3 patients returned to the Huntington Memorial Hospital for further care after their discharge from my wards. Three went to other public institutions, 3 made no further hospital visits anywhere, and 1 has been lost. Twelve patients were referred

*Read at a meeting of the New England Cancer Society at the Collis P. Huntington Memorial Hospital, Boston, November 7, 1940 (the statistics are correct to June 1, 1941).

†Assistant professor of neurosurgery, Harvard Medical School; associate professor of neurosurgery, Boston University School of Medicine; surgeon in chief for neurosurgery, Boston City Hospital.

times, two being complete and the others being differential sections. The fifth and ninth cranial nerves were divided or pinched through a posterior approach in 3 cases. In one operation, both nerves were divided, and in the other two the ninth was divided, and the sensory part of the fifth squeezed in a hemostat. The combination of the ninth cranial nerve and the upper three posterior cervical roots on one side was divided twice; these structures and the fifth nerve in addition were divided once. For these procedures, the approach was through a combined cervical laminectomy and hemiccipital craniotomy. In addition, 1 patient had a high (second cervical) chordotomy, and 1 a division of the cervical plexus in the neck.

Complications that influenced the choice and efficiency of the neurosurgical procedure were as follows: 2 patients, 1 of whom died, had a paralyzed larynx; 3 had osteomyelitis of the jaw (1 died); 3 had severe bleeding from the cancer; 2 had demonstrable brain and abdominal metastases (1 died); 2 had active local infections, one of which extended into the operative wound; 1 had a complete peripheral facial palsy on the involved side; 1 had an idiosyncrasy toward novocain (previously unknown) and died from that cause as he was being prepared for operation; and 2 were obviously very bad surgical risks.

The immediate results of the operative therapy were good and appeared to promise well for the future. Twelve patients were not relieved. Ten were not operated on, and 2 died within forty-eight hours of operation. One left against advice without treatment, and 1 was relieved by cobra venom for a month. One was relieved of pain but had severe cerebellar symptoms after operation, 13 were comfortable when they left the hospital, and 4 are still in the hospital following operation. Thus, of these 21 patients subjected to neurosurgical procedures, 13, or 62 per cent, were discharged from the hospital or died in the hospital relieved of pain. Of the 9 not operated on, 2, or 22 per cent, were relieved for a month or more. Within six months of their discharge, two thirds of this group had died. One may conclude, therefore, that at the time of leaving the hospital following treatment for pain, the patient with extensive cancer of the face, jaws and neck has almost 50 per cent greater chance of getting relief if he is operated on than he has with nonoperative therapy. Furthermore, since 41 per cent of the operated patients lived longer than six months after seeking neurosurgical relief, whereas only 22 per cent of the nonoperated group survived for the same period, it cannot be argued that the risk of operation is a deterrent to surgery. This immediate success attendant on denervation therapy doubt-

less accounts for the widespread belief in its efficacy, even when it is used inexcusably late in the course of the disease.

Twenty-four patients were followed to an end result of either death or established relief of pain (Table 1). The longest follow-up period was four years. So far as is known, this patient, who was not operated on, died unrelieved in Ireland. The shortest period was two months. This patient was not operated on and had partial relief following the drainage of an abscess in a carcinomatous mass in his neck. Two patients—both operated cases and both relieved of pain at their discharge from the hospital—have been lost. Four others are still under treatment in the hospital.

Only 1 of the remaining 22 patients is alive today. This one survivor—and this is the only such case in the entire group—is completely relieved of both pain and cancer three years and seven months after his neurosurgical operation and five years and one month after his first symptom. This man, who was referred by Dr. Charles Lund, was fifty-nine years of age and had a cancer of the cheek without local metastases. His pain started a year and three months after his first symptom and followed x-ray therapy. He was denervated three months later by division of the fifth and ninth cranial nerves in the posterior fossa. He was invalided for a number of months by cerebellar symptoms, but these have since disappeared. The relief of his pain was complete immediately after the operation and has remained so. The only other patient with a significant survival period is a woman of sixty, who also had a cancer of the cheek without local metastases. She was referred by the Huntington Memorial Hospital. A differential section of the sensory root of the fifth nerve was done five years after the start of pain and eight years after the first symptom. This patient's pain started before she received x-ray therapy and, indeed, was relieved by the first radiations. She had relief of pain for fifteen months after she was operated on. The tumor recurred, and she died in pain two months later.

Two other patients had complete relief for a short time before dying of their cancer; one for two months and the other for seven days. Both had local metastases. The patient with cancer of the parotid gland obtained no relief from division of the ninth and upper cervical nerves, and subsequently went to Philadelphia, where she received treatment by refrigeration. This also was not successful, and she eventually died thirteen months after the neurosurgical operation. Every other patient is dead or still under treatment. Of the former group, one lived for nineteen

months, but all the rest died within seven months after neurosurgical treatment. All died in pain and with no more than very temporary relief from these procedures

Certain conclusions relative to the treatment of the pain associated with cancer of the face, jaws and neck seem to me to be inescapable. These are that little if any relief can be expected from either medical or neurosurgical procedures that are initiated after the cancer has metastasized locally. If, despite that fact, surgical denervation is decided on, however, it carries no greater immediate risk than medical therapy and offers a much better chance of affording temporary relief.

It also seems reasonable to assume that therapeutic radiation of the malignant area is a significant factor in the causation of the pain that develops in association with cancer of the face, jaws and neck. Based on that assumption, the purpose, extent, effectiveness and pain-producing possibilities of any proposed x-radiation, as well as its relation to the possible effect that it may have on the cancer, should be carefully assessed in advance. It should never be countenanced when its effect is uncertain, or if this treatment is proposed because all other forms of therapy have been recognized as being useless.

Despite the discouraging results experienced in this series of patients, I am convinced that neurosurgery has its place in the treatment of cancers of the head and that it will prove useful when properly applied to this problem. The success following the early or premetastasizing denervation of the malignant area in 2 cases should be neither overlooked nor ignored. Under similar circumstances, it should be possible to duplicate this success in other patients. This will be possible, however, only when it is recognized that denervation

of the cancer-bearing area *must* precede the development of local metastases. This will mean that, as the malignancy of the tumor increases, the need for early effective denervation increases likewise, a requirement that if carried to its logical conclusion will, in certain cases, doubtless mean complete denervation by neurosurgery before the pain develops. This procedure was carried out in 1 case in this series. This will apply particularly to those cases that require large amounts of radiation, and offers not only the promise of future freedom from pain but, because of the local anesthesia associated with the denervation, the expectancy of greater efficiency in the treatment of cancer.

SUMMARY

The effect of neurosurgical procedures on the pain associated with cancer of the face, jaws and neck is analyzed.

Thirty cases are reported, in only 2 of which the patients had relief and were alive at the end of any significant follow up period.

Evidence is presented to demonstrate that the development of pain in such cancer bearing areas is associated with x-ray therapy.

Neurosurgical or any other procedures will almost certainly prove to be useless in the relief of this type of pain if provided only after the cancer has metastasized locally.

It is strongly recommended that surgical denervation of the cancer bearing areas in the face, throat, neck and jaws be performed as the first step in the treatment of the malignant growth, not only as a prophylaxis against later pain but also as an aid to greater efficiency in the therapy of the cancer because of the associated local anesthesia that is thus produced.

ASPIRATION BIOPSY, WITH A DESCRIPTION OF A NEW TYPE OF NEEDLE*

CLIFFORD C. FRANSEEN, M.D.†

BROOKLINE, MASSACHUSETTS

ASPIRATION has undoubtedly been used to withdraw fluids from various parts of the body ever since hollow needles were first added to the medical armamentarium, but the use of aspiration to obtain specimens from solid masses has

Forkner⁶ described the use of needle biopsy at the Collis P. Huntington Memorial Hospital in Boston to obtain material from lymph nodes. He used a dental broach, constructed on the principle of a fishhook, which he passed through the lumen

FIGURE 1. *Three Models of Mixer's Biopsy Punch.*

a much shorter history. About 1900 Dr. Samuel Mixer, of Boston, devised a biopsy punch that is still in use at the Massachusetts General Hospital to obtain specimens from brain tumors.¹ It consists of a hollow needle fitted with a blunt-nosed obturator, and has a hub that will receive the tip of a syringe for aspiration of tumor tissue. Figure 1 shows three models of this punch. Grieg and Gray² used aspiration biopsy to obtain specimens from lymph nodes as early as 1904. Guthrie,³ in 1921, reported the use of aspiration biopsy of lymph nodes and Barringer,⁴ in 1922, described a needle with a small cutting screw at the point, devised by Goeller, with which specimens were withdrawn from the prostate in cases in which the diagnosis was in doubt. Martin and Ellis⁵ state that needle biopsies have been used at the Memorial Hospital in New York since 1926. In 1927

of a 17-gauge or 18-gauge needle to secure more material than he could with the needle alone. Needle or punch biopsies did not come into common use, however, until about ten years ago, when the advantages and possibilities of the method became more widely recognized.^{5, 7-18}

Biopsy by aspiration through a large-bore needle has been more successful in obtaining specimens from deep-lying tumors than biopsy by a punch, since the latter often loosens pieces of tissue, especially in cellular tumors, the removal of which is not always successful. Aspiration with a syringe provides a good means of withdrawing a piece of tumor tissue, once it has been loosened, but difficulty is often experienced in causing a fragment of tumor to be loosened with the ordinary needle. No entirely satisfactory combination of a punch and aspiration has yet been devised because of the problem of making a mechanically satisfactory punch within the lumen of a needle in a size within practicable limits.

*From the Collis P. Huntington Memorial Hospital, the Palmer Memorial Hospital, and the Massachusetts General Hospital.

†Assistant in surgery, Harvard Medical School; assistant in surgery, Massachusetts General Hospital, Palmer Memorial Hospital and Collis P. Huntington Memorial Hospital.

An ordinary needle of 14 to 18 gauge with a tightly fitting syringe of 5-cc. to 20-cc. capacity often suffices to obtain a satisfactory specimen of a tumor, and enables the pathologist to make a diagnosis. Usually, however, only a few isolated tumor cells or small groups of cells can be obtained.

Aspiration biopsies, and have used it for about two years with considerable success. It was devised to obtain larger fragments of tissue, and at the same time to keep the needle simple and inexpensive.

By taking a 14-gauge needle with the obturator

FIGURE 2. Two Models of the Author's Needle for Aspiration Biopsy.
The lower one, with obturator withdrawn, is provided with a Luer-Lok hub.

With experience, some pathologists are willing to make a diagnosis on this meager material, but the problem is admittedly made easier when a larger specimen is provided for a study of the structure

FIGURE 3

Detail of the tip of the author's needle, with the obturator withdrawn (A) and inserted (B).

of the tumor as well as of the individual component cells.

Dissatisfaction with the material secured by needle biopsy is evinced by the introduction of numerous new models of punches and needles, each designed to obtain larger specimens. Punches or needles were developed by Hoffman¹⁹ in 1931, Hoffman¹² in 1933, Lindblom²⁰ in 1935, Lowsley²¹ in 1935, Corriero²² in 1937, Neumann²³ in 1938 and Silverman²⁴ in 1938.

I have also designed a needle (Fig. 2) for as-

piration biopsies, and making three bevels at the point, instead of the usual single bevel, a trocar point is made, and when the obturator is withdrawn, the needle is left with three cutting teeth (Fig. 3). When the needle is rotated, the teeth act as a trephine to core out pieces of the tumor. If suction is provided by a syringe simultaneously with the rotation, the loosened fragments are easily removed.

After application of an antiseptic to the skin, a wheal is made with novocain solution, and a minute stab wound is made with a sharp-pointed knife blade. The needle, with its obturator, is introduced until it is felt to engage the periphery of the tumor. The obturator is then withdrawn, leaving the three-toothed sheath in position. A 10-cc. or 20-cc. syringe is attached, and the plunger partly withdrawn to produce a vacuum. The plunger is grasped between the fifth finger and the hypothenar eminence of the right hand, and the thumb and index finger rest against the rim of the barrel of the syringe to hold the plunger partly withdrawn to maintain the vacuum. The barrel of the syringe and the needle are then rotated as a unit with the left hand and advanced into the tumor, whereas the right hand still holds the plunger tightly but permits the rim of the barrel to rotate between the thumb and forefinger.

Small pieces of tumor tissue are thus cored out, and the loosened fragments, together with some blood, are drawn into the shaft of the needle. The needle is advanced to the opposite side of the tumor, and the syringe and needle then drawn back out through the skin while suction is main-

eliminate this difficulty, a Luer-Lok needle-hub and syringe may be used, and the rotation made in the direction in which the lock is tightened.

A 10-cc. or 20-cc. syringe is most satisfactory for aspiration. A 5-cc. syringe may be used, but strong suction is more difficult to maintain with it. Larger

FIGURE 4. *Representative Biopsy Specimens Obtained by Aspiration.*

tained. On reaching the skin, air rushes in through the needle and carries the fragments of tissue into the barrel of the syringe. The plunger is withdrawn, and the pieces of tissue mixed with blood are scraped out upon a large piece of hard fine-grained filter paper. The liquid portion of the material is absorbed by the filter paper. With a Beebe loupe having a magnification of two and one-half times, the specimen is carefully examined, and the pieces of tissue are teased out from the blood clot with a very fine pair of forceps or with dissecting needles and placed in a heap on a small piece of filter paper. With the magnification provided by the Beebe loupe, the fragments of tissue stand out clearly in the blood clot. The tissue amassed on the small piece of filter paper is then placed in 10 per cent formalin or Zenker's solution and subsequently prepared in the routine manner for histologic examination.

If the connection between the syringe and needle is not tight, the needle may become loosened by the rotating motion and the vacuum destroyed. To

sizes are more awkward to handle. A disadvantage of many syringes is the small size of the lumen of the tip of the syringe, often considerably smaller than the lumen of the needle used. The pieces of tissue may, under these circumstances, be held up at the tip of the syringe. This difficulty may be eliminated by using a metal-tipped syringe, which is not only stronger, but permits an instrument maker to enlarge the hole in the tip if it is too small. Attention should therefore be paid to this point in purchasing a syringe for use in aspiration biopsies.

The method described above has been quite successful, and has, on occasion, succeeded when attempts to obtain a specimen by using an ordinary needle have failed (Fig. 4). It has proved more successful than an ordinary needle in obtaining specimens from tumors with a fibrous stroma.

INDICATIONS FOR ASPIRATION BIOPSY

Aspiration biopsy is employed with great circumspection, and the indications for its use have

gradually become more clearly defined. In ulcerated and superficial tumors, biopsy can satisfactorily be done by removal of a specimen by the usual methods from the surface. Aspiration biopsy, therefore, finds its place in nonulcerated and deeplying tumors. It is of greatest use in confirming the clinical diagnosis in inoperable tumors, usually antecedent to irradiation treatment, and it should not be employed in operable lesions unless the needle tract can be made to lie wholly within the tissue that is to be excised.

In cases of inoperable tumor, aspiration biopsy is often indicated for pathological confirmation of the diagnoses. By aspiration biopsy a specimen is obtained from many tumors that would otherwise have no biopsy because of the complexity of the procedure by the usual surgical methods, because of the prolonged hospital stay and additional expense or because of the patient's refusal through fear of a surgical procedure. Many patients have an aspiration biopsy performed in the outpatient department, and need not be admitted to the hospital for treatment until the pathological report has been returned. Many hospital days are saved by this practice, an important consideration when the number of beds available for treatment is very limited. An additional advantage is that irradiation treatment may be proceeded with at once after a diagnosis has been confirmed by aspiration biopsy. After biopsy by surgical incision, on the other hand, it is advisable in many cases to postpone treatment for several days, so that healing of the wound is not interfered with when large doses of x-ray or radium are planned.

Aspiration biopsy is exceedingly useful in confirming the presence of metastatic cancer in inoperable lymph nodes antecedent to irradiation treatment when the primary lesion is unknown, when it is inaccessible or less accessible to biopsy, or when it has previously been removed elsewhere and a pathological report is not available. These circumstances occur most commonly in cervical lymph nodes. When there is doubt whether enlarged operable cervical lymph nodes are involved by metastatic carcinoma in lesions of the lip and mouth, it is preferable to do a neck dissection without preliminary aspiration biopsy, if the primary lesion is controlled.

Aspiration biopsy is used only rarely when a diagnosis of lymphoma is suspected, since in the diagnosis and subclassification of tumors of this group it is desirable to have the architecture of the entire lymph node available for pathological examination. In these cases, therefore, a biopsy by surgical excision of a lymph node should always be performed.

In tumors of the parotid gland, aspiration biopsy is indicated only to confirm the diagnosis in inoperable tumors. If the tumor is operable, aspiration biopsy is contraindicated, since the complete specimen will be available for examination after excision, and spilling the cells along the needle tract by aspiration biopsy cannot be done without risk of recurrence unless the entire tract can be removed with the subsequent excision of the tumor. In cases in which the differential diagnosis between a malignant and a benign parotid tumor must be made, aspiration biopsy yields inadequate information.

In breast tumors, aspiration biopsy has also been reserved largely for inoperable lesions that it is planned to treat by irradiation. Carcinomas of the breast that are accompanied by inflammation fall into this class, since in these cases difficulty is often experienced in the healing of the wound of an open biopsy. In differential diagnosis of benign and malignant lesions of the breast, too frequently only a small focus of carcinoma in an otherwise benign lesion occurs, and an aspiration biopsy should not be relied on to find it. In these cases surgical exploration and frozen section are more reliable procedures. It has been suggested in the literature that aspiration biopsy is useful in determining whether or not palpable axillary nodes are involved in carcinoma of the breast. However, this does not seem to be a proper indication for aspiration biopsy, since in every operable carcinoma of the breast, the axillary lymph nodes should be removed whether they are palpable or not, because of the fallibility of clinical examination in judging whether metastasis has or has not occurred.

Aspiration biopsy has been reported to be of value in obtaining specimens from lung tumors. For this purpose I have used it to a very limited extent, because this procedure should be reserved for confirmation of the diagnosis in patients in whom no attempt at surgical removal is planned, and because of the risk of implantation in the chest wall and pleural cavity.

I have not used aspiration biopsy for abdominal tumors, since biopsy under direct vision through a small incision or through the peritoneoscope is a safer procedure.

Needle and punch biopsies have from their beginning been found useful in securing specimens from carcinomas of the prostate gland because of the difficulty in obtaining specimens by open operation when confirmation is desired. Although failure to obtain a satisfactory specimen may frequently occur, a successful result may save the patient a major operative procedure.

A carefully performed aspiration biopsy may occasionally be used with benefit in bone tumors if the history, physical examination and roentgenographic and blood chemical studies still leave doubt concerning the therapeutic procedure indicated. However, in tumors of the bones of the extremities, it is safer to perform an open biopsy distal to a tourniquet, to examine a specimen by frozen section and to amputate, if indicated.

There is rarely the need for an immediate diagnosis of a tumor by smear. Such diagnosis is rarely an emergency, and the pathologist should be given the opportunity for more careful study of larger specimens. The occasional desirability of an immediate diagnosis usually comes on the operating table, where a frozen section should be made available.

It should be emphasized that failure to obtain a positive pathological report by aspiration biopsy should not be interpreted as meaning that no tumor is present, or that the tumor, if present, is benign. Only a positive pathological report is significant.

SUMMARY

A needle employing the principle of the trephine is described for use in obtaining biopsy specimens by aspiration.

The greatest use for aspiration biopsy has been

found in confirming the clinical diagnosis in inoperable tumors antecedent to radiation treatment.

SPONTANEOUS RUPTURE OF THE SPLEEN IN INFECTIOUS MONONUCLEOSIS

Report of a Case

RICHARD B. KING, M.D.*

BOSTON

THAT rupture of the spleen is not a rare event is attested by the frequency with which such cases are reported. Although trauma, both severe and slight, heads the list of causes, one finds mention of the following conditions as etiologic factors: malaria, typhoid and typhus fever, echinococcal cyst, influenza, leukemia, polycythemia vera, hepatic cirrhosis, subacute bacterial endocarditis, tuberculosis, hemophilia and various acute infections. There are also many reports of spontaneous rupture of normal spleens.

In 1932 Attlee¹ reported a case of spontaneous rupture of the spleen in a twenty-three-year-old woman in whom a diagnosis of Vincent's angina had been made. From the clinical and laboratory reports, it seems highly probable that this was an

unrecognized case of infectious mononucleosis. Aside from this case, the literature contains no report suggesting rupture of the spleen in this condition. In view of the rarity of pathological reports concerning infectious mononucleosis, the following case is of sufficient importance to be reported.

CASE REPORT†

R. S., a 23-year-old consulting engineer, was admitted to the Heywood Memorial Hospital in Gardner, Massachusetts, on October 20, 1937, complaining of severe abdominal pain. Two and a half weeks before entry, he developed headache and tender cervical lymph nodes. One week before entry, he consulted a physician because of a very sore throat. The throat was found to be in-

†Reported through the courtesy of Drs. Harold C. Frey and Albert F. Lowell of Gardner, Massachusetts.

*Assistant in medicine, Massachusetts General Hospital

flamed, and the postcervical lymph nodes were enlarged and slightly tender. The patient continued to work although he felt very miserable, and experienced two shivering chills the day before entry, with profuse sweats that night. The morning of entry he got out of bed to go to the toilet, and was seized with a sudden agonizing pain in the abdomen radiating up to the sternum and through to the back. A physician was summoned and found the

discharged 3 weeks after entry, and in another 3 weeks was able to return to work, entirely recovered. Three years later he is reported to be well.

The results of the blood examinations are given in Table I. The preoperative blood films showed the platelets to be normal in number, postoperatively they were markedly increased. The sheep-cell agglutination test for infectious mononucleosis was positive in a dilution of 1:1256

patient in semishock, sweating profusely, with a pulse of 90 and a temperature of 97°F. He was taken to the hospital at once, and although extremely weak, he was able to walk to his room.

Physical examination showed the patient to be pale and sweating. He suddenly vomited blood streaked mucus. The pulse was 100, the blood pressure 130/65, and the temperature 98°F. The postcervical lymph nodes were enlarged and tender. The pharynx was inflamed and beefy, with two minute ulcerations on the posterior wall. The soft palate was inflamed and swollen. The heart and lungs were normal, although the patient complained of substernal pain on deep inspiration referred to the back. The abdomen was tense over the epigastrium with generalized tenderness in both flanks more on the left, and the patient complained bitterly of generalized crampy pain, most intense in the epigastrium. The urinary bladder was distended and the patient was unable to void. Neurologic examination was negative.

During the afternoon of the day of entry the patient's pulse rose to 110, the systolic blood pressure fell to 100, the temperature rose to 100°F, and the abdomen became distended and rigid with marked generalized pain and tenderness demanding laparotomy. Operation seemed advisable, and when the peritoneum was opened a large quantity of free blood containing clots was encountered. The appendix, which was found to be large and to contain a concretion, was removed. The spleen was felt on exploration to be markedly enlarged and was exposed through a second incision. The capsule was seen to be ruptured and to be draining blood freely. The spleen was removed. The surgical convalescence was entirely uneventful. The throat inflammation however was rather slow in clearing up, and a moderate generalized lymphadenopathy was noted. The patient was

The blood Hinton Wassermann and Widal reactions and the agglutination test for undulant fever were negative. Urinalyses were negative. Throat smears showed organism typical of Vincent's angina.

The pathological report by Dr. Shields Warren was as follows:

The spleen with partly stripped capsule measures 18 by 12 by 6 cm and weighs 660 gm. The capsule has been almost entirely stripped from one side, and reveals clotted blood forming a layer about 0.5 cm thick covering almost all this side. The other side of the spleen is covered by very slightly wrinkled, but otherwise smooth, shiny membrane. Section shows the spleen to be partly fixed. From the central portion, which is very soft, a moderate amount of pulp can be scraped. A few small hemorrhagic foci can be seen within the fixed tissue near the periphery. Microscopically the normal structure of the spleen is well preserved. The trabeculae are not enlarged. The follicles are distinct and of the usual size and present no inflammation or hyalinization. The sinusoidal structure is less prominent than normal owing to the large number of cells filling the sinuses. There is a relatively small amount of blood in the pulp. A diffuse distribution of powdery granules of hemosiderin is present. The pigment is found in the endothelial cells of the sinuses and in free phagocytic cells in the sinusoidal spaces. The cells filling the sinuses are free endothelial cells, which are most numerous large and small lymphocytes, plasma cells, polymorphonuclear leukocytes and a few undifferentiated cells suggesting myelocytes. Mitotic figures are rare. One portion of the spleen shows an area of unorganized hemorrhage. The microscopic picture is compatible with infectious mononucleosis.

Microscopic examination of the appendix shows es

essentially the picture of healed appendicitis. The serosal lymphatics contain a few clusters of lymphocytes. There are scattered lymphocytes, chiefly perivascular, in the muscularis. There is also a slight degree of fibrosis in the inner portion of the muscularis and the submucosa. The secondary nodules of the lymphoid tissue of the submucosa are sharply demarcated, and contain cells that are large, with rather vesicular nuclei. Mitotic figures occur, but they are no more numerous than one frequently finds. Some of the cells are less clearly defined than usual. The mucosa itself is essentially negative. There is nothing distinctive in the appendix that would associate it with infectious mononucleosis.

Infectious mononucleosis is by no means a rare disease, and if the condition is kept in mind, there should be no difficulty in recognizing it. The cardinal symptoms are fever, headache, sore throat, generalized malaise and tender, enlarged lymph nodes, regional or general. The spleen is usually palpable. The blood picture, although not pathognomonic, is highly suggestive. One always finds an increased percentage of large atypical lymphocytes, with a corresponding decrease in neutrophils. The cells may suggest those seen in acute leukemias, and similar cells may be seen in infectious jaundice. In infectious mononucleosis there is very rarely anemia, and no reduction in the number of blood platelets, in contrast to that prac-

tically always found in acute leukemia. Usually in infectious mononucleosis there is a leukocytosis, but it should be kept in mind that a small percentage of cases have a definite leukopenia. Furthermore, in differentiating this condition from infectious jaundice, one must remember that icterus occurs in infectious mononucleosis in a certain percentage of cases. Lymphadenopathy, however, always precedes the icterus, so that the two conditions may be easily distinguished. The sheep-cell agglutination reaction, which becomes positive in infectious mononucleosis after about the tenth day of the disease, makes the diagnosis certain.

Although rupture of the spleen in this disease is very rare, its occurrence is serious enough to demand that infectious mononucleosis be treated with respect, and not on an ambulatory basis.

SUMMARY

A case of rupture of the spleen in the course of infectious mononucleosis is reported, together with the detailed pathological report of the spleen.

MEDICAL PROGRESS

THE CAUSES AND TREATMENT OF EDEMA*

LAURENCE B. ELLIS, M.D.†

BOSTON

EDEMA is an abnormal collection of fluid in tissue spaces. This may be a very localized phenomenon, or it may be generalized throughout the body. Few physical signs lend themselves so well as edema to physiologic analysis and interpretation and therefore it is not only frequently possible but highly desirable to understand the mechanism of edema production in any given case, so that the underlying cause can be specifically attacked and treatment can be made genuinely effective. There is a constant exchange of water and electrolytes and certain nonelectrolytes between the blood stream and the tissue spaces through the capillary walls. This interchange is kept in bal-

ance and the amount of tissue fluid is kept constant by two opposing pressures. The hydrostatic pressure within the capillaries tends to drive fluid out of the capillaries, whereas the osmotic pressure exerted within the capillaries, largely by the plasma proteins to which the capillary walls are normally nearly impermeable, tends to draw it back. Therefore, if either the hydrostatic capillary pressure is increased or the plasma colloid osmotic pressure is diminished, a condition favoring the development of edema results. A factor of importance not generally appreciated is the pressure exerted by the elastic subcutaneous tissues.¹ This tends to limit the amount of edema that forms in any given case, and also is in part responsible for the location of the edema—that is, other things being equal, edema fluid collects where the skin and subcutaneous tissues are relatively lax, as in the periorbital region. Under certain circum-

All articles in this series will be published in book form; the current volume is *Medical Progress: An annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Associate in medicine, Harvard Medical School; junior visiting physician, Boston City Hospital.

stances, protein escapes through the capillaries into the tissue spaces, or is laid down in abnormally great amounts, thus raising the colloid osmotic pressure within the tissues. A more accurate expression, therefore, of the balancing of the opposing pressures between capillaries and tissue spaces would be: hydrostatic blood pressure in capillaries plus tissue osmotic pressure equals subcutaneous tissue pressure plus plasma osmotic pressure; normally, the hydrostatic blood pressure and the plasma colloid osmotic pressure are the important factors involved.

In addition, the total electrolyte concentration of body fluids is significantly concerned with the water balance of the body. The organism attempts to maintain the composition of these fluids constant, even at the expense of gain or loss of water itself. Hence anything that seriously affects the electrolyte balance of the body, so that sodium or chloride is retained, may under certain conditions lead to edema. Excellent discussions of this problem are presented by Gamble⁶ and by Peters.⁷ Many of the factors affecting electrolyte and water balance are still unknown, but knowledge of the role of the endocrine glands in this regard is increasing.

CAUSES OF EDEMA

Increased Capillary Permeability

Toxic states—such as those from burns, bites, heat and cold, allergy, as manifested by urticaria or angioneurotic edema, and inflammation, as in cellulitis—all produce edema because of increased capillary permeability to protein and the local escape of fluid high in protein content into the tissue spaces, with a resultant increase in tissue colloid osmotic pressure. In some of these types of edema, the local release of a toxic substance, possibly histamine,^{8,9} may be responsible. This has led to the clinical attempt to "desensitize" persons who are subject to urticarial disturbances from exposure to cold, serum sickness, insulin hypersensitivity and so forth, as well as certain types of headaches, by administering graded small doses of histamine⁶⁻⁸ and by attempts to neutralize the histamine by giving histaminase,⁷⁻¹⁰ a histamine-destroying enzyme found in the gastrointestinal mucosa. As yet clinical reports of the use of histaminase have not been convincing enough to establish its value in this regard unequivocally, and the use of histaminase rests on no good physiologic foundation.¹¹

Generalized edema occurs in the early stages of acute glomerular nephritis. It is now believed by most authorities that the edema is a result of

the widespread capillary damage that occurs in this condition, with increase in capillary permeability.

Increased Hydrostatic Intravascular Pressure

Venous backpressure. Venous thrombosis or varicose veins are the commonest cause of unilateral or unequal edema of the lower extremities. Obstruction to the superior vena cava not uncommonly occurs with disease involving the superior mediastinum, such as aneurysm or tumor, and gives rise to a characteristic clinical syndrome. Inferior vena cava obstruction is much rarer but also results in a typical picture. Portal-vein obstruction, of course, characteristically leads to ascites. When dependent edema occurs, it tends to develop late and is due in part to the pressure of the ascitic fluid on the vena cava, and in part to the hypoproteinemia, which is generally present.

When the venous pressure is generally raised, it almost always means congestive heart failure of the right-sided type. In addition to edema, distention of the peripheral veins is usually found, with jugular veins that remain engorged even in the semirecumbent position, and an enlarged tender liver. The only exception to heart failure as the cause of such a generalized increase in venous pressure is cardiac tamponade, which may be produced by fluid in sufficient quantity in the pericardial sac, or a constricting pericarditis.

Arteriolar dilatation. When arterioles become widely dilated, blood pressure within the capillaries increases and a condition favoring edema formation exists. This may occur regionally in connection with nerve injuries, since involvement of somatic nerves may be accompanied by vasomotor paralysis, although vasomotor spasm is of more frequent occurrence under these circumstances. Vasomotor paresis may also be of central origin. For example, it has been shown that hemiplegia of cerebral origin is usually accompanied by diminished vasomotor tone on the affected side,¹² and edema of moderate degree is not uncommon over this area.

It is possible that one of the factors involved in the generalized edema that may occur in beriberi is peripheral vasodilatation due to involvement of the vasomotor system.¹³ Since, in this condition, heart failure may also occur, there may exist edema and a high venous pressure at a time when the circulation time is normal or shortened, a combination of events that is most unusual and is found in only two other types of congestive heart failure, that caused by hyperthyroidism and that secondary to arteriovenous aneurysm.

Lymphatic Obstruction

Chronic obstruction of the lymphatics draining an extremity gives rise to edema that is difficult to distinguish from that consequent on venous obstruction. It tends to be rather more brawny in character, and there is no color or temperature change. One remarkable tendency manifested by patients with such edema is the frequent development of superficial infections of the involved extremity, resembling lymphangitis or cellulitis.

Edema from lymphatic obstruction is not very rare. Although filariasis is unknown in this section of the country, and neoplastic lymphatic obstruction is usually dramatic and well recognized, a not very uncommon, but usually unrecognized, cause of edema of one or both legs is lymphatic obstruction due to pelvic inflammatory disease, which may have been inactive for years. Since such disease is also prone to lead to deep thrombophlebitis, the differentiation of the cause of the resulting edema may be difficult or impossible. An uncommon but interesting type of lymphedema is that known as Milroy's or Meige's disease,¹⁴ a familial affection of unknown etiology, involving one or both lower extremities.

Hypoproteinemia

Hypoproteinemia may occur as the result of deficient protein intake, of increased protein loss or of impaired formation of the plasma proteins. Severe grades of malnutrition in persons whose diets are unusually deficient in protein may lead to edema. In certain disturbances of the gastrointestinal tract (sprue, diarrhea and the changes due to massive resections and to the congestion of heart failure), the absorption of many vital food substances may be impaired, and in some cases the absorption and utilization of protein itself are interfered with. Many patients of this type who show hypoproteinemia have either deficient diets or disturbances of liver function as important causative factors.

Not uncommonly, a deficiency in protein intake is a contributory cause of an edema the major etiology of which is traceable to some other disease, for example, cardiac edema.¹⁵

Another important cause of hypoproteinemia is, of course, loss of plasma protein, and the commonest and most important channels through which this is lost are the kidneys. Edema resulting from this cause is known as "nephrotic edema" and is seen in the nephrotic stage of glomerular nephritis, in "lipoid nephrosis" and in amyloid disease. The correlation between clinical findings, physiology and pathology has been especially imperfect in this condition. It is generally accepted that protein is chiefly excreted through the glomeruli, and yet it

is frequently difficult to demonstrate clear-cut pathologic changes in the glomeruli, although recently by special staining methods glomerular lesions have been shown to occur in most cases of nephrosis. A controversy has long raged about whether lipoid nephrosis is a specific disease entity or a stage of glomerular nephritis, and if a specific disease, whether a primary renal disturbance or metabolic disorder, as contended by Epstein. It is not relevant to the subject at hand to enter into this controversy, except to mention that there has recently been reported a good deal of work bringing forward evidence of various sorts that the plasma and urinary proteins in nephrosis and even in the nephrotic stage of nephritis may be qualitatively different from normal plasma proteins.¹⁶⁻²⁰ Whether this difference is primary and possibly a cause of the proteinuria, or whether it is merely the result of the prolonged drain of chronic protein loss on protein formation is not yet established.

Other less common channels by which blood proteins may be lost, which may under certain circumstances be very important, are serous effusions, such as ascites, burned surfaces and, especially, hemorrhage, acute or chronic.

The factor in the causation of decreased plasma proteins that has received attention most recently is deficient protein formation. Although the sites of formation of all plasma proteins are not conclusively established, it is probable that the liver is specifically concerned, undoubtedly with fibrinogen and probably with albumin synthesis, and it is known that disease of the liver is frequently accompanied by hypoproteinemia.^{21, 22} Lowering of the plasma proteins is frequently considered a clinical test of poor liver function. Hypoproteinemia is usually found in advanced portal cirrhosis and is often a chief contributing factor in the ascites and edema found in this condition.

Low plasma proteins are not uncommonly present in patients with congestive heart failure. There are several possible factors involved. One, already mentioned, is the deficient protein intake of many of these patients. A second is protein loss through the kidneys and, to a lesser extent, in pleural and peritoneal effusions. A third is impaired protein formation, probably due to depression of liver function consequent on the hepatic congestion and anoxia. Another cause of the lowering of the protein concentration in the plasma is dilution of the blood, owing to hydremia, especially in patients in whom diuresis has or is about to set in.²³

Disturbances of Electrolyte and Water Balance

The composition of tissue fluid is kept extraordinarily constant, and even when it collects in

abnormal amounts, the change is quantitative rather than qualitative, since its composition remains essentially unaltered. The chief base or cation concerned is sodium, which makes up about 140 of the total of 150 millicivalents per liter. Anything that tends to increase the total amount of sodium in the body favors the production of edema, and conversely anything that depletes the total body sodium leads to dehydration. It is difficult for a normal person to change his body sodium materially because of the immediate and accurate adjustment the kidney is able to effect, but in any condition already present that predisposes to edema, it may be then possible to lessen the sodium present in the body, and hence the amount of edema, by withholding salt from the diet or by facilitating its excretion, as by the administration of an acid-producing salt, such as ammonium chloride or nitrate.

The role of the endocrine glands in electrolyte and water balance is being increasingly studied. Interestingly enough, many of the hormones of the endocrines that have been investigated have been found to lead to retention of sodium and chloride and hence of water, thyroxine being the major exception. Perhaps the most striking in this respect is the adrenocortical hormone. It is well known that a deficiency of this substance, as in Addison's disease, leads to sodium loss, rise of blood potassium, dehydration and shock. Administration of this hormone and of the synthetic desoxycorticosterone to normal and adrenalectomized animals, and to human patients with Addison's disease, causes sodium and water retention,²¹ and cases have been reported in which the giving of desoxycorticosterone in therapeutic doses to patients with Addison's disease has resulted in generalized edema and even in hypertension, hypervolemia, pulmonary edema and heart failure.²⁵⁻²⁶ It is possible that the hypertension and edema of Cushing's syndrome is associated with an excess secretion of adrenocortical hormone.²⁷

Most of the hormones of the ovary and testis (estrone, progesterone and testosterone) have been shown to produce salt and water retention.²⁸ An interesting clinical state is cyclic menstrual edema.²⁸⁻³¹ This rare condition is apparently an aggravation of a normal physiologic change in which many women retain significant amounts of water during the periods of maximal estrone secretion, that is, at the time of ovulation and even more during the days just preceding menstruation. The treatment of cyclic menstrual edema is not very satisfactory, although in individual cases success has been reported from the administration of the anterior-pituitary-like hormone obtained from the urine of pregnant mares and from the use of

Emmenin (an estrone containing preparation), as well as ammonium chloride and a low salt diet.³¹

During pregnancy, the majority of women retain water, and in a considerable percentage edema actually results. When such women in addition suffer from hypoproteinemia due to protein malnutrition or ingest an excess of salt, edema is especially likely to occur, and according to Strauss,³² in a certain number the clinical picture of pre-eclamptic toxemia develops. Weiss et al.³³ are of the belief that toxemia of pregnancy necessitates the presence of some unknown factor, apparently elaborated in the placenta.

It has been known for a long time that lesions of the posterior portion of the pituitary gland or some adjacent structure in the hypothalamus may lead to diabetes insipidus or polyuria due to failure of tubular reabsorption of water. The exact location of the lesion producing these conditions has been in dispute, some contending that it is in the base of the brain and others that the neurohypophysis is responsible. Dandy's³⁴ report demonstrates that when the posterior portion of the pituitary gland is deprived of its nerve supply through section of its stalk, diabetes insipidus may result. Extract of the posterior pituitary gland (pituitrin) or more specifically its pressor fraction, Pitressin, counteracts this disturbance, and its antidiuretic effect resides in its power to promote renal tubular reabsorption of water.³⁵⁻³⁶ It is also known that diabetes insipidus does not occur in the absence of the anterior portion of the pituitary gland, and there is evidence³⁷ that anterior-pituitary extract exerts a diuretic effect. It can be said, therefore, that normally the posterior portion of the pituitary gland exerts an antidiuretic and the anterior portion a diuretic effect, and that these opposing actions are in equilibrium.

Lack of thyroid hormone, as clinically seen in myxedema, gives rise to retention of tissue fluid high in protein content. As shown by Byrom,³⁸ this is due to an increase in the mucoprotein of the intercellular regions, the architectural skeleton that holds the cells together. As a result of this increase in protein in tissue fluid, its colloid osmotic pressure is increased, salt and water are retained and edema or more properly myxedema may result. The edema of hypothyroidism is thus of a unique type.

The administration of thyroid extract, or the clinical condition of hyperthyroidism, leads to the opposite effect—loss of interstitial protein, fluid and dehydration.

The effect of insulin in promoting water retention has been the occasion of a good deal of investigation and speculation. It is well known that

following the institution of insulin therapy in diabetic patients prompt gain of weight may occur, much of which is due to water retention.³⁹ This is apparently because the storage of glycogen is accompanied by water retention, whereas when fat metabolism predominates water is lost.

Clinical cases of edema following insulin administration have occasionally been reported. The causation of the edema is probably diverse. Rarely hypersensitivity to insulin, especially to protamine insulin, develops, with resulting urticaria or angioneurotic edema.³⁹ The edema that has been reported following diabetic coma and acidosis may well be due to the hypoproteinemia that frequently occurs. There is no evidence that insulin exerts any significant effect on sodium or chloride metabolism.⁴⁰

Hence, the endocrine glands undoubtedly play an important role in electrolyte and water balance. Most of them operate through their effect on sodium or chloride or protein retention. Posterior-pituitary extract is unique in that it apparently causes specific retention of water itself through its effect on the renal tubules. In the light of present knowledge, however, it cannot be said that endocrine disturbances are a frequent cause of marked clinical edema, or that therapy with hormonal preparations is often of value in the treatment of edematous states.

When edema occurs in patients with vitamin deficiencies the usual cause is hypoproteinemia due to protein malnutrition. Another type is the edema seen in beriberi, which has already been discussed. This may in part be due to congestive heart failure secondary to the effect of the deficiency on the heart itself, and in part to peripheral vasodilatation caused by vasomotor paresis. The present evidence indicates that this particular disturbance is largely or entirely the result of lack of vitamin B₁ and is relieved by the administration of thiamin. There may occur, however, edema in patients with deficiency of the vitamin B complex, which is not relieved by thiamin or by riboflavin but is cured by the giving of whole yeast.⁴¹ In other words, this edema, of undetermined nature, is due to the lack of an unidentified substance present in yeast. There is no evidence that lack of the other vitamins is a factor in the formation of edema.

Edema occurs not uncommonly in severely anemic patients, and this symptom, together with the breathlessness such patients usually manifest, has frequently led to the mistaken diagnosis of heart disease or heart failure as the primary cause of the clinical picture. It is true that anemia may precipitate heart failure in a patient with underlying heart disease, but edema as usually

seen in patients with anemia is of a different origin. Sometimes it is caused by hypoproteinemia, owing to an associated protein deficiency; often, however, the edema seen in anemia is explained by none of these causes.⁴² The severity of this is in general in proportion to the degree of anemia, and is aggravated by the administration of sodium salts. Occasionally, however, patients with untreated pernicious anemia fail to exhibit edema until after the institution of therapy and the beginning of improvement. The cause of this type of edema is still obscure.

TECHNICAL CLINICAL METHODS FOR EVALUATION OF EDEMA

The etiology of edema can usually be determined by a careful history, a physical examination and a routine urinalysis. Occasionally, however, further laboratory assistance must be called for. The most useful of these tests, and one that should be easily available, is determination of the plasma or serum proteins. These normally vary from about 6 to 8 gm. per 100 cc. It has been shown that, as they become diminished, water accumulation in the tissues increases because of the lowered plasma osmotic pressure, and when they reach a level as low as 5.0 to 5.5 gm., this fluid retention is usually manifest as edema.⁴³ A more accurate gauge than the total plasma proteins is the determination of the levels of the albumin and globulin separately. Normally, albumin makes up about 60 per cent of the total protein, and globulin 40 per cent. Any lowering of the plasma proteins is mainly at the expense of the albumin fraction, which, having the smaller molecule, is more easily lost through the capillary or glomerular walls but also for the same reason has a greater effect on osmotic pressure. A lowering of the plasma albumin from its normal of about 5.0 gm. to 2.5 gm. or below is likely to result in edema.

A simple and highly accurate estimate of the total plasma proteins can be reached by determining the plasma or serum specific gravity, which varies in direct proportion to the protein.⁴³ There are now available several ingenious methods by which the plasma specific gravity can be quickly and accurately determined.⁴⁴⁻⁴⁶ These, in the main, depend on the speed of fall of a drop of plasma or serum through a liquid of known density with which it is immiscible, or the insertion of such a drop into a liquid with a differential density varying from light to heavy and determining the level in the liquid the drop attains. Since the determination of hypoproteinemia is so frequently of value, it is to be anticipated that the estimation of plasma proteins will soon come to be a routine laboratory procedure that in clinical usefulness will

rank with nonprotein-nitrogen and blood-sugar determinations

The direct measurement of venous pressure can be carried out quickly and easily by the insertion of a needle (18 to 19 gauge) into an antecubital vein, connecting it with a manometer filled with saline, and relating the height of the saline column to the estimated level of the right auricle.⁴⁷⁻⁴⁸ This normally is either 10 or 15 cm of water or less, depending on whether the reference point is the front or back of the chest.

In most cases of congestive heart failure, this procedure is unnecessary, since the cause of the edema is evident and an estimate of the venous pressure can be made by determining the height to which the jugular veins remain filled with the patient in the sitting or semireclining position. However, there are times when one cannot be sure whether edema of the lower extremities is due to local venous obstruction or the generally increased venous pressure of cardiac failure, in which the findings of an elevated venous pressure in the arm will answer the question. Moreover, by measuring the venous pressure in two places, as for example in each arm or in an arm and a femoral vein, venous obstruction sometimes can be diagnosed and localized.

Estimations of the various blood electrolytes are of greater value in states of dehydration than in edematous conditions, since, as already stated, in edema they may be quantitatively normal.

TREATMENT OF EDEMA

The treatment of edema, like that of most other pathologic states, resolves itself into an attempt to attack the underlying cause directly, and into nonspecific measures.

Nothing need be said here about the specific treatment of localized allergic or inflammatory edema, of that resulting from venous obstruction, or of the edema of congestive heart failure.

The logical way of treating edema due to hypoproteinemia is, of course, to raise the plasma proteins. When these are low because of diminished intake they can be easily increased by giving a diet adequate in protein. When the difficulty is caused by increased loss, results from high protein feeding are less satisfactory but still the most logical procedure. If liver disease is responsible for impaired production, the value of feeding excessive protein is problematical.

Recently, experimental work has been reported regarding the intravenous administration of amino acids for the purpose of maintaining protein balance and of raising low plasma protein levels.⁴⁹⁻⁵¹ The results are interesting and suggestive but

still in the experimental stage, and more investigation is needed before the clinical value and safety of this procedure can be considered proved.

A successful way of temporarily raising plasma proteins is by the actual administration intravenously of the proteins themselves. For a long time this could be accomplished only by whole blood transfusion and this is still the procedure of choice if anemia exists. But if there is no deficiency in red cells, plasma transfusions, which are now in use and becoming increasingly available, are to be preferred, and the various methods for obtaining highly concentrated plasma solutions are rapidly being improved to a point where they will be widely applicable and the side reactions will be minimal.⁵²

For many years, it has been advocated that a substitute colloid be administered that will be nontoxic and will have the osmotic effect of plasma proteins. Acacia appeared to fulfill these requirements, and has been and is extensively employed. A few years ago, the use of acacia was largely abandoned, chiefly because of the many bad results reported, some of which were undoubtedly due to improperly purified and prepared acacia solutions. It was also believed that the repeated administration of acacia to a patient could in the long run be deleterious, since it might act by further depressing the plasma protein level. Recently, several reports from the Mayo Clinic¹ and elsewhere of the use of acacia with excellent results have revived interest in this substance, and further investigation of its value now seems warranted.

The first of the nonspecific measures to be attempted in the treatment of any widespread edema is the exclusion of sodium chloride and other sodium-containing salts from the diet, and possibly the attempt at increasing sodium excretion by the administration of an acid-producing salt, such as ammonium chloride (6 to 10 gm daily).

Urea in oral doses of 45 to 90 gm a day is also sometimes effective. Intravenously administered hypertonic solutions, such as glucose, sucrose, sorbitol and magnesium sulfate, may produce a diuresis, although a temporary one at best. These substances, in particular magnesium sulfate, are especially of value in conditions in which there are cerebral symptoms associated with cerebral edema. It should be remembered that all hypertonic solutions, if given rapidly in fairly large amounts, temporarily increase blood volume and hence act as a strain on a weakened heart, and also that the late effect of glucose may be exactly the reverse of that desired, that is, water retention with increase of edema may occur. More-

over, it has been reported that intravenous sucrose may cause renal damage.⁵⁵

Of the drugs used as diuretics the most popular at present, and deservedly so, are the mercurials, of which merbaphen (Novasurol), mersalyl (Salyrgan) and Mercupurin are the best known. These should be given intravenously if possible, are tolerated intramuscularly, but cannot be administered subcutaneously. They are practically nontoxic. A rare case of intolerance to them may occur. I have seen but one case of renal irritation out of a great many thousand injections. If effective in a patient, they can be given repeatedly without harm. Many patients have had hundreds of injections over a period of years, at weekly or semi-weekly intervals. The dose is 1 to 2 cc.; larger doses are usually inadvisable. The exact mode of action of these drugs is still in dispute. A recent report⁵⁶ suggests that under certain circumstances the blood volume may be considerably increased prior to diuresis, and these authors therefore suggest, to avoid the possibility of undue strain on the heart, the administration of smaller doses (0.5 cc.) thrice daily.

The inconvenience of the intravenous injection of the mercurial diuretics has led to an attempt to find other routes of administration. Suppositories containing the drugs are available but, although often effective, have not proved entirely satisfactory because of the rectal irritation that often results. A recent report⁵⁷ of an effective oral preparation is promising, but further work is required before its value can be considered established.

Although the mercurial diuretics are on the whole the most effective and have received especial attention in the last few years, the xanthine group should not be forgotten. Although theophylline itself is the most potent of the xanthine group, its tendency to produce nausea has led to its use mainly in combination with other salts, such as theophylline sodium acetate, 5 to 10 gr. thrice daily, and theophylline ethylene diamine (Aminophylline), 1½ to 3 gr. thrice daily. The latter, however, is of greater clinical value when used as a bronchial dilator or vasodilator than as a diuretic. Theobromine, usually administered in combination with sodium salicylate (Diuretin), 40 to 60 gr. daily, is mild but well tolerated. More effective is theobromine calcium salicylate (Theocalcin), 20 to 40 gr. daily.

SUMMARY

A scheme has been presented for the evaluation of clinical edema in accordance with the underlying disturbance involved; the various causes

of edema and of certain disturbances of the electrolyte and water balance have been discussed; certain technical aids in the assessing of the nature of the edema have been considered; and its treatment has been described.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27251*

PRESENTATION OF CASE

A two-year-and-nine-month-old boy was well until two months before entry, when he contracted what was considered to be pertussis. At the same time the siblings were said to have suffered from pertussis. For the first three weeks of his illness he was up and about, had a good appetite, but lost weight, and for the last month was so ill that he had to remain in bed. His temperature rose to 102°F. daily. Paroxysms of coughing continued, but the whoop disappeared. For the three days before entry, the cough was much worse, and hospitalization was advised.

The family and past histories were irrelevant.

Physical examination revealed an extremely emaciated boy without any subcutaneous fat and with marked loss of muscular tissue. He was quite pale and ill, with a severe, loose cough, producing moderate amounts of very foul purulent sputum without blood. He was dyspneic and slightly cyanotic. His skin was dry and rough, and there was a slight hyperkeratosis about the hair follicles. The eyes were normal; the ears and nose were normal. The abdomen was distended and tympanitic. The liver and spleen could not be felt. There was no tenderness or spasm. There was definite clubbing of the fingers and toes. There was a pronounced Harrison's groove, but no great enlargement of the costochondral junction. The heart was normal. The right lung was hyper-resonant, and breathing was greatly exaggerated. There were numerous loud adventitious sounds referred from the opposite side; there were no fine rales on the right. The left chest was dull to flat throughout, particularly over the left base and in the axilla. Breath sounds were diminished and replaced by numerous loud rales, rhonchi and bubbling sounds. Tactile and vocal fremitus were increased over the areas of dullness. There was amphoric breathing in the area of flatness in the left lower axilla.

The urine was normal. The blood showed a moderate secondary anemia, no leukocytosis and a normal differential count. A 1:1000 tuberculin

test was negative. Type 23 pneumococcus was isolated from the throat.

X-ray films of the chest revealed complete opacity on the left, with a suggestion of cavitation at the left base. The right lung showed a diffuse fine mottling consistent with, but not diagnostic of, tuberculosis. X-ray films of the long bones revealed osteoporosis.

From entry the patient was desperately ill, the fever remaining between 101 and 103°F. The cough was extremely severe, producing large amounts of foul sputum. Repeated examinations of the sputum for acid-fast bacilli were negative. The patient was given the usual supportive treatment, including two small transfusions of citrated blood and a transfusion of blood serum. He was placed in an oxygen tent the last few days of life. The patient's condition was too precarious to allow any further diagnostic or therapeutic measures, and he died six days after entry.

DIFFERENTIAL DIAGNOSIS

DR. DONALD KING: I have not yet seen the x-ray films, but wish to give you my preliminary reactions on reading the summary of the case. There are four points I shall make.

In the first place, it is obvious that the boy had a pulmonary abscess or multiple abscesses. In this clinic at the present time we are not using the term "gangrene of the lung," but I am sure that in many clinics a case like this, with high fever, very foul sputum, marked loss of weight and rapid progression to death, would be so classified.

My next point is concerned with the etiologic organism of this abscess. We are told that Type 23 pneumococcus was isolated from the throat and that no tubercle bacilli were found, but we are given no further bacteriologic data. I do not believe that Type 23 pneumococcus would give the abscess and foul sputum, and we have no reason to believe that a Friedländer bacillus or yeast or other fungus was present; hence we must assume, I believe, that the pulmonary abscess was caused by the group of anaerobic mouth organisms, including spirochetes, fusiform bacilli, vibrios and cocci. Just how these organisms found their way into this patient's lung and set up the infection is not clear.

Thirdly, what about the relation of whooping cough to lung abscess? We must assume that the boy had whooping cough, because he and his brothers and sister whooped. But lung abscess is a very rare complication of this infection. There is no mention of it in the literature, and in our series of 212 cases of pulmonary abscess, none were associated with pertussis. Of course, in bron-

*This case is presented through the courtesy of the Children's Hospital, Boston.

chiectasis the story is different Whooping cough is frequently given as the cause of this disease, and in our series of 400 cases 9 per cent were said to have followed pertussis Present opinion is that two factors are necessary for the production of bronchiectasis: bronchial obstruction, which may be partial or complete, and infection It has been suggested that in whooping cough enlarged mediastinal lymph nodes are responsible for partial bronchial obstruction I should like to get some help from the x-ray men and Dr. Farber regarding this point The textbooks do not help They talk about bronchitis and emphysema associated with whooping cough, but do not mention enlarged nodes

DR JAMES R LINGLEY: We see very few chest films of children with whooping cough However, our impression is that inflammatory lymph nodes, unless tuberculous, are rarely seen by x ray

DR KING: Then it is up to you, Dr Farber Do enlarged lymph nodes occur commonly with whooping cough, and is it possible that they give bronchial obstruction and therefore lead to bronchiectasis? And, in the case that we are considering, could enlarged nodes have been a possible factor in producing the pulmonary abscess?

DR SIDNEY FARBER: I should think not, in a case of uncomplicated pertussis

DR KING: Then neither the roentgenologist nor the pathologist can give any support to this theory.

Finally, what other causes were there for the abscess? In any child of two years and nine months with an abscess or persistent lung disease, one wonders about the inhalation of a foreign body, and we must consider this possibility, although we have no evidence for it Also we should think of congenital lung changes, possibly cystic, as a basis for later suppuration There is again no evidence in this case If this were an adult we should think of bronchial tumor, either benign or malignant, but such a diagnosis seems very unlikely in a child

We now come to the interpretation of the x-ray films, and the points in which I am interested are, first, whether the heart was displaced toward the left, giving evidence of atelectasis, or toward the right, making one suspect the presence of a large amount of fluid in the left pleural space; and secondly, what we are to do about the shadows in the right lung, which are interpreted as "fine mottling consistent with, but not diagnostic of, tuberculosis"

DR LINGLEY: The films show an extensive destructive process on the left side, with multiple

cavities; the diaphragm is slightly elevated on the left, and there is a slight displacement of the heart to the left The trachea likewise is a little displaced

DR KING: But no evidence of what one would consider real atelectasis or drowned lung, with bronchial obstruction?

DR LINGLEY: The collapse must have been of slight degree

DR KING: Do you want to help as to the presence of fluid?

DR LINGLEY: I think there is very little, if any, fluid.

DR KING: Certainly the story and physical findings seem to be against fluid.

DR LINGLEY: On the right side, there is mottling throughout the entire lung, a miliary process quite consistent with miliary tuberculosis.

DR KING: Of course, I am "on the spot" with this miliary lesion. Here is a child with a negative tuberculin test, using a 1:1000 dilution, and repeated negative smears for tubercle bacilli in the sputum. In an adult I should think of sarcoid disease, miliary carcinoma and possibly silicosis or yeast or fungus infection In this child, with such an x ray film, it is difficult to make any other diagnosis than tuberculosis in the right lung The negative tuberculin test could be explained because the child was moribund, and dying from overwhelming infection If the tuberculous process were primarily hematogenous and the process in the lung had not yet gone on to cavity formation, the sputum might still have been negative. I do not believe that pulmonary suppuration on the left side spreading to the right would give this roentgenologic picture Is that so, Dr. Lingley?

DR LINGLEY: Yes

DR KING: Everything considered, I should make the diagnosis of multiple pulmonary abscesses and miliary tuberculosis

DR TRACY B MALLORY: Are there any other suggestions or alternative diagnoses?

DR HAROLD L HIGGINS: I should think that the miliary process might come from plain bronchiectasis, it seems more or less localized

DR KING: It is diffuse from the top to the bottom of the right lung

DR MALLORY: Dr. Lingley, you do not know the answer, it may be fair to ask your opinion.

DR LINGLEY: Tuberculosis is my diagnosis

DR KING: All tuberculosis?

DR LINGLEY: Yes

DR KING: We have to have something more than tuberculosis to give foul sputum I do not believe tuberculosis by itself would give that.

DR. LINGLEY: The patient probably had secondary infection, but the main process, I believe, was tuberculous.

DR. KING: If it was tuberculosis, the patient might have had tuberculous nodes that gave bronchial obstruction.

CLINICAL DIAGNOSES

Pertussis, convalescent.

Bronchopneumonia, secondary (Type 23 pneumococcus).

Lung abscess, left lower lobe.

Chronic malnutrition, with multiple vitamin deficiencies.

Tuberculosis?

DR. KING'S DIAGNOSES

Multiple pulmonary abscesses.

Miliary tuberculosis.

ANATOMICAL DIAGNOSES

Pulmonary tuberculosis, with cavitation, left lower lobe.

Miliary tuberculosis.

Lung abscess, left lower lobe.

Bacteremia, terminal (Type 23 pneumococcus).

Acute bronchopneumonia, right (Type 23 pneumococcus).

Vitamin A deficiency.

Pertussis, convalescent (clinical history).

PATHOLOGICAL DISCUSSION

DR. FARBER*: I had to go back to 1935 to find a case of tuberculosis that did not have the diagnosis of tuberculosis stamped all over it.

This patient did have tuberculosis, and there were certain other findings. The child was very much emaciated, a finding not characteristic of tuberculosis in early life. There was a peculiar dryness of the skin, which was remarked on in the history and which was considered by those clinicians who saw the patient to be suggestive of a deficiency disease, the exact type of which was not mentioned. At autopsy we found some evidence of vitamin A deficiency, as shown by metaplasia of the lining epithelium of the trachea and bronchi, although no change was present in the ducts of the pancreas or the renal pelvis. The vitamin A levels, determined during life from the blood and at autopsy from the liver, were low.

In the lowermost portion of the left lung was an area of caseation, and the lymph glands on that side showed the classic spread of tuberculosis, the

characteristic picture of the lymph-node component of the primary lesion. In the right lung the picture was much more that of miliary tuberculosis, but that was not all. Here we also found massive acute pneumonia caused by a Type 23 pneumococcus, the organism recovered from the heart's blood at the time of autopsy. A deeper cut showed the cavity on the left, which Dr. King discussed and which was a mass of necrosis and caseation. Almost the entire lower lobe on the left was involved in the process. Whether a foreign body had been there, or aspiration of food had occurred into a small area of tuberculous infection, I cannot say from the findings at autopsy; it is highly probable, however, that some such factor must have been added to the tuberculous process to produce this kind of lesion and the type of sputum described.

A minimal number of lesions were found in other parts of the body. There were miliary tubercles in the liver, kidney, spleen, bone marrow and many other organs of the body. This type of spread is a hematogenous one. One section of the lung shows an area in which the process is breaking into a bronchus by direct extension and destruction of the bronchial wall. Another shows a much more characteristic type of Ghon lesion, with a small area of consolidation just beneath the pleura, surrounded by satellite tubercles, and with spread to the regional lymph nodes. There was a tuberculoma of the cerebellum—a lesion rarely seen at the present time. Still another rare lesion at autopsy was massive mesenteric lymphadenitis caused by the tubercle bacillus.

I might add just one point concerning the relation of pertussis to a lesion of this kind. Pertussis may accelerate the tuberculous lesion that has existed previously, as is well known, or may be responsible for aspiration of vomitus, food or foreign bodies during paroxysms and thus bring about secondary damage to the lungs, quite apart from the initial pathologic process. In pertussis, the uncomplicated disease is a superficial one involving the cilia of the upper respiratory tract. The major symptom is brought about by the presence of the organisms in the cilia, with interference with ciliary activity. The lymph nodes at the hilum of the lung become involved only when complications due to secondary invaders occur.

A PHYSICIAN: Do the enlarged nodes narrow the bronchus?

DR. FARBER: No; not to any important degree, except in cases of chronic bronchopneumonia.

DR. KING: We really have three conditions here—the abscess, the pneumococcal infection and the tuberculosis.

*Assistant professor of pathology, Harvard Medical School; pathologist, Children's Hospital, Boston.

CASE 27252

PRESENTATION OF CASE

First Admission. A sixty-nine-year-old construction worker entered the hospital complaining of severe frontal headaches of five weeks' duration.

One week before entry, the headache shifted to the temporal regions; it included first the left and then the right, and was accompanied by a sore throat, a fever of 102°F. and redness and swelling of the face to the point where both eyes were closed. Furthermore, there was exquisite tenderness of the left scalp.

On examination the left face was swollen, and the left scalp acutely tender. There were cardiac enlargement, aortic regurgitation and a Corrigan pulse. The blood pressure was 180 systolic, 70 diastolic. A rectal examination was said to have been negative. The white-cell count was 12,800; the blood Hinton reaction was positive, the spinal-fluid Wassermann reaction negative.

Within a few days, the facial swelling subsided somewhat, and an unusual prominence of both superficial temporal arteries was noticed. Although pulsation was not visible, it was palpable, albeit somewhat reduced, and tenderness was present along the main trunks and branches. Pressure on the carotid arteries relieved the headache. The temperature was found to rise regularly in the afternoon. A biopsy specimen was taken from one of the arteries, and histologic examination disclosed temporal arteritis. Three weeks after admission, the patient's symptoms had subsided spontaneously and he was discharged.

Second Admission (two months later). In the interval the patient had felt perfectly well except for slight constipation, which had been relieved by laxatives. Two days before admission, he noticed anorexia and began to pass large amounts of gas by mouth and rectum. Nothing further occurred until a few hours before entry and half an hour after a rather small, loose, bowel movement. At the time, the patient was bending over and was seized with a constant, sharp, crampy hypogastric pain accompanied by profound weakness and the passage of more gas by mouth and rectum. He lay down and applied a hot-water bottle to his abdomen, with some relief, but an hour later suffered a shaking chill, followed by fever and sweating. The patient's physician was called and recorded a temperature of 102.7°F. and soreness in the left lower quadrant; he advised immediate hospitalization. At the time of admission, the pain was more intense, arising in waves every five to ten minutes and breaking within twenty seconds; it seemed to originate in the left lower quadrant, shifting to the umbilical region and right lower

quadrant. Each time an attack occurred the patient had a desire to move his bowels and complained that it hurt to shift his legs. He denied nausea, vomiting and dizziness and said that he had gained weight since his last illness, when he had lost 40 pounds.

The additional physical findings were as follows: The patient appeared acutely ill. The blood pressure was 100 systolic, 40 diastolic. In the distended abdomen there was diffuse tenderness, most marked in the lower portion, and spasm was noted in the left lower quadrant. Peristalsis was hypoactive except during the attacks of pain. On rectal examination, a 3-cm. to 4-cm. cauliflower-like mass was palpable on the right anterior wall of the rectum, 9 cm. from the anal orifice; its surface bled freely.

The temperature was 102°F., the pulse 89, and the respirations 20.

The urine showed a + test for albumin. The blood showed a red-cell count of 4,600,000 with a hemoglobin of 75 per cent, and a white-cell count of 20,000. The nonprotein nitrogen of the blood serum was 29 mg. and the protein 6.5 gm. per 100 cc.; the chlorides were 105.2 milliequiv. and the carbon dioxide combining power 25.7 milliequiv. per liter. The stools were liquid, thick and gray black, and gave a ++++ guaiac reaction.

A flat abdominal x-ray film showed dilated, air-filled loops of small intestine, particularly on the left side. The colon was moderately dilated. A film of the chest taken with a portable machine was negative.

The patient was given a 500-cc. blood transfusion, and a Miller-Abbott tube was passed. During the next nine days he improved tremendously; feces and flatus passed per rectum, the abdominal distention subsided, the white-cell count dropped to 12,000, and the temperature fell. Gradually a tender mass, definitely not the one felt rectally, localized in the left lower quadrant. A proctoscopic examination two weeks after admission revealed a hard, movable, ulcerated lesion on the anterior rectal wall, 12 cm. from the anus. A biopsy of the mass showed adenocarcinoma, Grade II. Twelve days later an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JOHN D. STEWART: May we see the x-ray films?

DR. GEORGE W. HOLMES: The films of the chest show no evidence of metastasis to the lungs. They do show enlargement of the left side of the heart, with some tortuosity of the aorta. The position of the diaphragm is normal. This film was taken

to determine whether there was free air in the abdominal cavity, and there is no evidence of it. The next film shows moderately dilated loops of small bowel in the left upper quadrant, a rather characteristic picture of gas-filled, moderately dilated loops of jejunum. I do not want you to put too much weight on that statement. It may be ileum, but I think it is jejunum. Then, after the passage of the Miller-Abbott tube, the films show deflation and the disappearance of a large amount of gas in the intestinal tract. I do not see any evidence pointing to the nature of the obstruction.

DR. STEWART: It seems clear to me at the outset that this patient's abdominal pain was intestinal colic, and other causes of abdominal pain can therefore be passed over. Furthermore, it seems clear that the intestinal colic was due to obstruction and not to other causes such as enterocolitis or food poisoning.

The causes of acute intestinal obstruction may be divided into three general groups, the neurogenic, the mechanical and the vascular. In this case, the neurogenic causes can be eliminated at once, in my opinion, because of the severe crampy abdominal pains, the bloody diarrhea and the development of spasm and tenderness in the left lower quadrant. Then, if the obstruction was either mechanical or vascular in origin, did strangulation enter the picture? The manifestations of acute mechanical intestinal obstruction vary, depending on the extent of interference with the blood supply to the bowel. There is some reason in this particular case to suspect strangulation: the decline in blood pressure, the rapid onset of severe pain, the development of localized tenderness and spasm and, subsequently, the development of a mass in the left lower quadrant, all of which are consistent with a process interfering with the blood supply to the bowel. However, the same findings also fit with an interference with bowel function coming from a primary vascular accident. As Dr. Holmes pointed out, there are dilated loops of small intestine. There is also gas in the large intestine. That, to my mind,—since this patient was not given an enema, in which way air may be injected into the colon,—suggests an incomplete obstruction to the lumen of the bowel, probably in the small intestine rather than in the large. I might say at this point that I do not believe that the carcinoma of the rectum, which the patient had, contributed to the symptoms that brought him into the hospital at the second admission. If we conclude that there is evidence of strangulation and of incomplete obstruction to the lumen of the bowel, a fair diagnosis to make is a primary vascular accident of some sort, either

embolic or thrombotic. As to what the primary lesion was in the vascular system we can only speculate. There was a possible source of emboli in the aortic lesion that this man had, and perhaps in the arteriosclerotic lesions that he probably had.

At this point we turn to a consideration of the episode that brought him into the hospital the first time. This was apparently a very bizarre picture, the exact nature of which I cannot make out. There were protracted headache and an illness associated with the loss of 40 pounds in weight; the culminating symptoms were fever, sore throat and swelling of the face, the description of which sounds like a cellulitis of the face; there was spontaneous subsidence of the evidence of infection and localization of the process in the temporal arteries, and the diagnosis of temporal arteritis was made by biopsy. Whether the general infectious process involving the arteries was syphilitic in type, whether it was nonspecific, whether it was due to a streptococcus or to some other bizarre lesion such as periarteritis nodosa, I do not see how we can say. However, I am inclined to explain the abdominal symptomatology on the same basis. If we do that, we are brought to a diagnosis of acute intestinal obstruction caused by intestinal infarction based on primary arterial disease. In addition, we know that the patient had carcinoma of the rectum. He probably had syphilis, and he had aortic regurgitation, myocarditis and hypertension.

This patient's course in the hospital bore out the judgment of those who had charge of the case. It is fair to say, however, that the evidence presented to us in the text makes it hard to see why they withheld operation at the time of admission to the hospital the second time. As a rule, early cases of acute intestinal obstruction are treated by fluid therapy, transfusion and operation, particularly when there is evidence that suggests strangulation, as in this case.

We are left to explain the mass in the left lower quadrant. If we make a diagnosis of intestinal infarction, we must assume that the mass was an infarcted, devitalized loop of intestine or a perforated loop with abscess. An unusual feature of this man's symptomatology at the second admission was the absence of vomiting. Usually, when there has been such a severe acute disturbance of bowel function, there is vomiting in connection with the cramplike pain. A diagnosis of intestinal infarction takes one "way out on a limb," but it seems to me that that is the most probable diagnosis in this particular case. The possibility that the patient had a lesion such as intussusception of the sigmoid, possibly in relation to a polyp, must be

considered, but I dismiss that from the diagnostic possibilities in my own mind

DR TRACY B MALLORY Dr Stewart has brought out clearly the fact that this is a complicated case, the symptomatology of which certainly cannot be explained by the presence of carcinoma of the rectum, which we know the patient had

DR F DENNETTE ADAMS Would Dr Stewart consider the possibility of a diverticulum above the cancer, with rupture at the time that the episode occurred?

DR STEWART I did consider that in going over the case. There were premonitory symptoms of two days' duration before the onset of the acute abdominal pain. Furthermore, an elevation of temperature at the time of the onset of abdominal pain suggests some general process or some inflammatory process apart from the acute lesion, but I do not see how we can make that diagnosis any more definite. I should be a little surprised to find that the patient had gas in the small intestine if the obstruction originated in the sigmoid, but I suppose it is a possibility.

CLINICAL DIAGNOSES

Carcinoma of the rectum
Diverticulitis?
Ulcerative colitis?

DR STEWART'S DIAGNOSES

Acute obstruction of the small intestine, due to infarction
Carcinoma of the rectum
Aortic regurgitation and chronic myocarditis
Serologic syphilis

ANATOMICAL DIAGNOSES

Diverticulitis of the sigmoid
Carcinoma of the rectum
Temporal arteritis

PATHOLOGICAL DISCUSSION

DR MALLORY So-called "temporal arteritis" is still a quite mysterious lesion. It is usually seen in people beyond the age of fifty, is generally bilateral and generally clears up spontaneously after varying lengths of time, and the histologic picture is rather characteristic. In the wall of the blood vessel, usually in the media, one finds con-

siderable numbers of foreign body giant cells, but to me the lesion does not look like periarteritis nodosa. It affects larger vessels than periarteritis nodosa usually does. It is a little more similar in appearance to the acute stage of Buerger's disease but again varies somewhat from that, and its uniform appearance in elderly people is very much against Buerger's disease. Whether patients suffering from temporal arteritis have similar vascular lesions elsewhere in the body is still unknown. I am not aware of any absolutely proved example, but it seems probable that they may occur.

DR EDWARD F BLAND The Mayo Clinic¹ reported about a dozen cases, and as I recall there was no direct relation to syphilis in any of these, either histologically or clinically. In one case a radial artery was also suspected of being involved at the same time, but this was not definitely established. Dr Adams had a patient here last year with this condition of temporal arteritis; I saw another patient last year, and one was reported at the Boston City Hospital² two years ago. They all followed the same clinical course and recovered after a period of months.

DR MALLORY In one case from which we had a biopsy specimen, the patient turned up later with intermittent claudication in the legs, but it was never possible to establish a diagnosis as to the vessels of the leg.

DR RICHARD H SWEET At operation it was discovered, of course, that the small bowel obstruction had disappeared. We noted that the tender mass was an area of diverticulitis of the sigmoid above and entirely separate from the cancer. The sigmoidal diverticulitis had perforated, and a thick inflammatory mass was adherent to the bladder. We did not see any evidence of fecal contamination. We therefore made a localized excision of that area with a proximal colostomy, brought the lower end below the sigmoidal lesion out in the lower portion of the wound,—somewhat as one does in the first stage of a Lahey excision of the rectum in two stages,—and left the rectal carcinoma to be dealt with later.

BIOPSY IN TUMOR DIAGNOSIS

SINCE the choice of surgery or radiation in the therapy of tumors hinges largely on an exact knowledge of the type of neoplastic cell present, biopsy is essential, even when one is reasonably sure that a tumor rather than another type of lesion is involved.

If the tumor is easily reached, incisional biopsy is usually simple and best suited to supply material for accurate diagnosis. Not always, however, is the tumor accessible; when it is deeply seated, one may resort to the aspiration of tumor cells or bits of tissue, and various methods have been suggested. One of the most satisfactory is that described in a paper in the present issue of the *Journal*. The procedure is one that traumatizes tissue but little and is fairly simple to carry out.

All methods of aspiration biopsy have certain inherent difficulties. Sometimes it is difficult to tell whether the tumor itself and not adjacent tissue has been removed. Furthermore, since the diagnosis of the pathologist frequently depends not only on the types of cells but also on the relation of tissues, a clear idea of general structure and tissue relation can be obtained only with difficulty from small amounts of tissue. This disadvantage is particularly great in cases of tumors of the breast or of the bone. Pathological diagnosis based on tissue removed by aspiration of various types should be guarded, and the findings should be weighed carefully with the clinical and roentgenographic evidence.

THE PROBLEM OF THE THREE EDWARD WARRENS

WHEN three men, all living at the same time, and all making distinct contributions to American medical literature, have the same name, without middle initials, the bibliographic confusion a hundred years later is not inconsiderable. When one, moreover, is closely associated with the ether controversy, another writes concerning the life of the man who, next to Morton, played the leading role in the ether demonstration in 1846 and a third became an Egyptian *Bey*, the demand becomes insistent to identify the individuals and their works. The problem, in part, was solved correctly four decades ago in the Army Medical Library; nevertheless, such are the vagaries of mind and the unreliability of man that the same institution now falls into error, and the world of bibliography must be again set right. To do so, however, is not by any means easy. Of one Edward Warren we know much, of another a moderate amount, but of the third, who gives the most difficulty, we know scarcely anything.

The easiest problem concerns the Edward Warren (1828-1893), *Bey*, a romantic Virginian, one of the most bizarre figures in the annals of American medicine, whose life has been well summarized by Howard A. Kelly in the *Dictionary of American Medical Biography* (1928). Born in 1828, in North Carolina, he became, in order, a country

doctor, a medical editor, a professor of surgery, a medical inspector of the confederate states during the Civil War, the chief surgeon of the general staff of Ismail Pasha in Egypt, a practitioner in Paris and a chevalier of the Legion of Honor. After a life on three continents he settled in Paris, and died there in 1893. An account of his unusual adventures is told in his book, *A Doctor's Experiences in Three Continents* (Baltimore, 1885), which consists of a series of letters to his friend, Dr John Morris, of Baltimore. Known as Edward Warren, *Bey*, he is easily identified and correctly referred to in the first series of the *Index-Catalogue*. Unfortunately, he is confused with another Edward Warren in the third series of the same great catalogue. His picturesque career, unique in American medicine, and based on his work in the swamps of Carolina, on the shores of the Chesapeake, on the borders of the Nile and in the quarters of the Seine, has been thoroughly depicted in numerous biographical sketches of the man. The *Bey* was not a contributor to the literature of the ether controversy, nor was he related, except possibly distantly, to the Warren family of Boston.

The other two Warrens with the given name of Edward were both Warrens of New England. The better known was Edward Warren (1804-1878), younger brother of the John Collins Warren (1778-1856) who performed the ether operation at the Massachusetts General Hospital on October 16, 1846. His well-known *Life of John Collins Warren* (Boston, 1860) was published in two volumes. He also wrote a biography of his father, *Life of John Warren, M.D.* (Boston, 1874). The reference to this book is the one incorrectly given in the third series of the *Index-Catalogue*. This Edward Warren graduated from Harvard College in 1826 and the Harvard Medical School in 1829, won the Boylston Prize in 1838 and in 1839 and, as noted above, wrote two important biographies. He was not a member of the Massachusetts General Hospital staff in 1846, and although forty two years old at the time, there is no record of his being in the hospital on October 16 of that year. He took no part in the

ether controversy, although he wrote an admirable account of it a decade later in the biography of his elder brother. This Edward Warren is most often confused with Edward Warren, *Bey*.

The identity of the third Edward Warren forms the real problem. His name stands out clearly on an important and rare ether pamphlet, *Some Account of the Letheon; or, Who Was the Discoverer?* (Boston, 1847). A second and a third edition, with a slight change in the title, were also issued in 1847. This publication by Warren must not be confused with the pamphlet by W. T. G. Morton, *Circular, Morton's Letheon* (Boston, 1846), five editions of which were issued in 1846 and 1847, this being Osler's first anesthesia item in his "Bibliotheca Prima," published in *Bibliotheca Osleriana* (Oxford, 1929). The Warren pamphlet was issued by Edward Warren, Morton's business associate and, according to Ford, a nephew of John Collins Warren. He came from Palmyra, Maine, and was closely associated with Morton during the early days of ether anesthesia. He is the same Edward Warren who contributed to the April 28, 1847, issue of the *Boston Medical and Surgical Journal* a note, "The Letheon and Dr. Wells" and to the May 19, 1847, issue a letter, 'Ethereal Inhalation.' Dr. Wells's claims as discoverer." The first of these two notes aroused the interest of Edward Warren, the physician and brother of John Collins Warren, who in a letter in the July 21, 1847, issue of the *Boston Medical and Surgical Journal* stated that he was not the author of the article, but that it was written by "a non-medical gentleman connected in this business with Mr. Morton." Dr. Warren, moreover, stated that his sympathies were entirely with Dr. Jackson, thus at that time differing from his older brother, the surgeon at the first operation.

This "non medical gentleman" was referred to as 'Mr Morton's agent,' an epithet he vehemently protested against in the July 28, 1847, issue of the *Boston Medical and Surgical Journal*. Little more is known of this third Edward Warren, not a physician in 1846, but whose name is so intimately associated with that of Morton. We can at least dissociate him from the *Bey* and from the

Pathological diagnosis based on tissue removed by aspiration of various types should be guarded, and the findings should be weighed carefully with the clinical and roentgenographic evidence.

THE PROBLEM OF THE THREE EDWARD WARRENS

WHEN three men, all living at the same time, and all making distinct contributions to American medical literature, have the same name, without middle initials, the bibliographic confusion a hundred years later is not inconsiderable. When one, moreover, is closely associated with the ether controversy, another writes concerning the life of the man who, next to Morton, played the leading role in the ether demonstration in 1846 and a third became an Egyptian *Bey*, the demand becomes insistent to identify the individuals and their works. The problem, in part, was solved correctly four decades ago in the Army Medical Library; nevertheless, such are the vagaries of mind and the unreliability of man that the same institution now falls into error, and the world of bibliography must be again set right. To do so, however, is not by any means easy. Of one Edward Warren we know much, of another a moderate amount, but of the third, who gives the most difficulty, we know scarcely anything.

The easiest problem concerns the Edward Warren (1828-1893), *Bey*, a romantic Virginian, one of the most bizarre figures in the annals of American medicine, whose life has been well summarized by Howard A. Kelly in the *Dictionary of American Medical Biography* (1928). Born in 1828, in North Carolina, he became, in order, a country

monest cause of death so soon after delivery is hemorrhage into the peritoneal cavity from rupture of the uterus, with subsequent shock.

It is reported that in this case one ampule of pituitary extract was given after the bag had been introduced. This is very poor obstetrics. Minimum doses repeated at regular intervals can do no harm, but an ampule at any time during labor before the baby and placenta are delivered is not advisable.

DEATH

OSBORNE—EDWARD D. OSBORNE, M.D., of New Bedford, died May 19. He received his degree from Howard University College of Medicine in 1907. He was a member of the Massachusetts Medical Society and the American Medical Association.

His sister survives him.

MISCELLANY

TUBERCULOSIS IN MENTAL HOSPITALS

Dust swept under the sofa disturbs no one—until it is discovered, nor does tuberculosis hidden from public view. It is well to be reminded that more than 5 per cent of the people who die of tuberculosis annually in the United States are in mental hospitals. Scant attention has been paid to this sector of the problem for which reason an article on tuberculosis in mental hospitals (Pollak, M., Hummel, A. V., and Turov, I. L. Tuberculosis in mental hospitals. *Am Rev Tuberc* 43:373-387, 1941) commands the attention of health workers, hospital authorities and physicians. An abstract of the article follows.

The Peoria (Illinois) State Hospital with an average daily census of 2575 patients, has had a tuberculosis revision since 1905. X-ray examination of the 56 patients assigned to it showed that 16 per cent had no tuberculosis. Thus, of the resident patients in the hospital at the beginning of the survey, only 47 (187 per cent) were known to have tuberculosis.

From the beginning of the survey it was obligatory to take a chest roentgenogram on all patients who were transferred to the infirmaries irrespective of whether tuberculosis was suspected or not. In the course of the study there were surveyed 2156 patients in residence: 766 newly admitted patients and 477 employees. Tuberculin tests of these groups (all but about 4 per cent were tested with tuberculin) showed positive reactions in 94.6 per cent of resident patients, 80.6 per cent of receiving ward patients and 57.3 per cent of the employees. Parenchymal lesions were revealed by x-ray examination in 11.2 per cent of resident patients, 7.4 per cent of receiving ward patients and 1.6 per cent of employees. The majority of the resident patients and less than half the receiving ward patients were over fifty years old. The great majority of employees were under fifty years of age.

The percentage of the tuberculous increased with the length of stay of the patients. Of the tuberculous employees, one half developed the disease after five years of service.

About 10 per cent of the tuberculous patients in the receiving wards were committed from tuberculosis sanatoriums and about 14 per cent were known to have tuberculosis at the time of admission. The remaining cases were discovered in the course of the survey.

This study bears out what has been found in other

studies namely that when the physical examination alone is depended on, tuberculosis is at times diagnosed when it does not exist and overlooked at others even in the terminal stage. One investigator found that 38 per cent of the patients on the tuberculosis wards had no tuberculosis. In another hospital for mental diseases, 2 undiagnosed cases were found in 50 autopsies.

The different infection rates in the three groups can be attributed to the different age groups, and the high percentage of positive reactors among the resident patients chiefly to advanced age. It should be considered also that patients in this study come largely from the low income group in which infection and morbidity rates are known to be high.

The significant difference in the percentage of tuberculosis among resident (11.2 per cent) and receiving ward (5.7 per cent) patients indicates that many of the patients develop tuberculosis while they reside in the institution.

The rationale of spending money on tuberculosis prevention among the psychotics, who already represent a tremendous burden on society, was seriously questioned by some authorities in the course of our study. The fact, however, that 6.9 per cent of our tuberculous patients have already been discharged or paroled by January 1, 1940 shows that some of these patients have an opportunity to spread their disease in their own family and community after they return home. The possibility of the spread of the disease from these patients to the employees has also to be considered seriously. For these reasons, the money spent on tuberculosis prevention must be considered as a prudent investment on the part of hospital authorities.

The treatment of the tuberculous psychotic differs in no way from that of the mentally normal, namely, rest. The chief aim of treatment is to produce a negative sputum, and, therefore, collapse therapy is used even if the patient's mental condition seems to be entirely hopeless. Patients under shock therapy deserve special consideration—3.2 per cent of such patients developed tuberculosis either during the course or after the treatment. Patients should be x-rayed immediately before undergoing shock therapy and frequently thereafter.

Should tuberculous psychotics be centralized in one institution? The disadvantage (from the state's standpoint) is that the transportation of patients is costly and that it entails a hardship when the family of a patient has to travel a long distance. Under decentralization each hospital has to have on its staff at least one physician who is well trained in psychiatry as well as phthisiotherapy. The training of such physicians promises worthwhile contributions to the psychiatric as well as to the tuberculosis field.

The author's conclusions are as follows:

Tuberculosis is a problem of first order in every mental institution.

Patients suffering from tuberculosis are admitted to these institutions in a fairly large percentage without being so diagnosed. In addition to these, a relatively large percentage of patients develop tuberculosis while in residence again without their disease being recognized.

Owing to the contagious nature of tuberculosis mental institutions should develop a definite and systematic tuberculosis-control program employing the tuberculin test and x-ray study in diagnosis. These examinations should be conducted on all newly ad-

mitted patients immediately after admission and on the resident patients at least once annually.

Collapse therapy should be fully utilized in the treatment of the tuberculous psychotic, irrespective of the patient's mental deterioration.

Patients selected for shock therapy should be x-rayed before treatment is begun and re-rayed at frequent intervals during and after such treatment.

Employees coming in close contact with the patients should be x-rayed every three months, and the tuberculin reactors among the other personnel at least once annually. — Reprinted from *Tuberculosis Abstracts* (June, 1941).

RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR APRIL, 1941

DISEASES	MARCH 1941	APRIL 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	1	0	0
Chicken pox	1181	1286	1139
Diphtheria	16	11	14
Dog bite	1314	907	937
Dysentery, bacillary	1	24	9
German measles	522	56	211
Gonorrhea	315	268	412
Lobar pneumonia	391	521	573
Measles	4018	2463	3303
Meningococcus meningitis	8	5	15
Mumps	1492	756	1106
Paratyphoid B fever	6	3	9
Scarlet fever	877	756	1111
Syphilis	419	479	498
Tuberculosis, pulmonary	267	189	298
Tuberculosis, other forms	29	19	32
Typhoid fever	2	10	5
Undulant fever	13	4	3
Whooping cough	807	625	726

*Based on figures for preceding five years

RARE DISEASES

Anterior poliomyelitis was reported from: Pittsfield, 1; total, 1.

Diphtheria was reported from: Fall River, 1; Foxboro, 1; Northbridge, 1; Saugus, 3; Springfield, 4; Tyngsboro, 1; Waltham, 2; West Springfield, 1; Worcester, 1; total, 15.

Dysentery, amebic, was reported from: Worcester, 1; total, 1.

Dysentery, bacillary, was reported from: Framingham, 1; total, 1.

Infectious encephalitis was reported from: Dedham, 1; Scituate, 1; Winthrop, 1; total, 3.

Malaria was reported from: Fort Banks, 1; total, 1.

Meningococcus meningitis was reported from: Boston, 1; Camp Edwards, 1; Milton, 1; Springfield, 1; Wareham, 1; Worcester, 3; total, 8.

Paratyphoid B fever was reported from: Haverhill, 1; Malden, 3; Salem, 2; total, 6.

Pellagra was reported from: Winchendon, 1; total, 1.

Pfeiffer bacillus meningitis was reported from: Framingham, 1; total, 1.

Septic sore throat was reported from: Andover, 1; Beverly, 3; Boston, 10; Fall River, 4; Framingham, 1; Hanson, 2; Lynn, 1; Milton, 1; total, 23.

Tetanus was reported from: Swampscott, 1; total, 1.

Trachoma was reported from: Boston, 1; Lynn, 1; total, 2.

Typhoid fever was reported from: Chelsea, 1; New Bedford, 1; total, 2.

Typhus fever was reported from: Chelmsford, 1; total, 1.

Undulant fever was reported from: Acton, 1; Adams, 1; Amherst, 1; Leominster, 6; Lowell, 1; Littleton, 1; Montague, 1; Walpole, 1; total, 13.

The second case of anterior poliomyelitis for the year was reported in April.

Chicken pox, diphtheria and whooping cough were reported slightly above the five-year averages.

Dog bite, which has been increasing steadily since January, showed a record high figure for this month.

Bacillary dysentery showed low incidence.

Lobar pneumonia was reported at the lowest figure since the corresponding month in 1933.

Mumps and German measles were reported highest in any month since 1936.

Measles, which has been climbing steadily since October, was reported still above the five-year average.

Meningococcus meningitis, typhoid fever, paratyphoid B fever, tuberculosis (pulmonary), and tuberculosis (other forms) were reported below the five-year averages.

Undulant fever showed an all-time record high figure for any one month.

Scarlet fever, which has been climbing since August, was reported below the five-year average.

NOTICES

ANNOUNCEMENT

DR. ROBERT L. MASON announces the removal of his office from 12 Bay State Road, Boston, to 75 Bay State Road, Boston.

MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

Medical Inspector, School Department,
\$500 a Year, Westfield

Director of State Civil Service, Ulysses J. Lupien, has announced that competitive examinations are to be held on July 22 to find eligibles for appointment to the position of medical inspector, School Department, Westfield.

The entrance requirement is as follows: applicants must be registered physicians under the Massachusetts Board of Registration in Medicine. The subjects and weights of the examination are as follows: training and experience, 2; practical questions, 3; total, 5. Applicants must obtain a grade of 70 per cent in each subject in order to become eligible. The last date for filing applications is Tuesday, July 1, at 5 p.m.

MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

School Physician, School Department,
\$1000 a Year, Leominster

Director of State Civil Service, Ulysses J. Lupien, has recently announced that a competitive examination is to be held on July 25 in order to find eligibles for appointment to the position of school physician, School Department, Leominster.

The entrance requirement is as follows: applicants must be registered physicians under the Massachusetts Board of Registration in Medicine. The subjects and weights of the examination are as follows: training and experience, 2; practical questions, 3; total, 5. Applicants must obtain a grade of 70 per cent in each subject in order to become eligible. The last date for filing applications is Monday, July 7, at 5 p.m.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The next written examination and review of case histories (Part I) for Group B candidates will be held in various cities of the United States and Canada on Saturday, January 3, 1942, at 2:00 p.m. Candidates who successfully complete the Part I examinations proceed automatically to the Part II examinations held later in the year. Applications for admission to Group B, Part I, examinations must be on file in the secretary's office not later than October 6, 1941. Applications for Group A must be in the secretary's office by March 1, 1942.

The general oral and pathological examinations (Part II) for all candidates (Groups A and B) will be conducted by the entire board, meeting at Atlantic City, New Jersey, immediately prior to the 1942 meeting of the American Medical Association.

As previously announced in the board booklet, this fiscal year (1941-1942) of the board marks the close of the two groups of classification of applicants for examination. Thereafter, the board will have only one classification of candidates, and all will be required to take the Part I and Part II examinations. For further information and application blanks, address Dr. Paul Titus, secretary, 1015 Highland Building, Pittsburgh (6), Pennsylvania.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Story of Clinical Pulmonary Tuberculosis By Lawson Brown, M.D. 8", cloth, 411 pp., with 1 portrait. Baltimore: Williams and Wilkins Company, 1941. \$2.75

A Manual of Allergy for General Practitioners By Milton B. Cohen, M.D., director of the Asthma, Hay Fever and Allergy Foundation, visiting physician in allergy, St. Alexis Hospital, Cleveland, Ohio. 12", cloth, 156 pp. New York: Paul B. Hoeber, Incorporated, 1941. \$2.00

Arthritis and Allied Conditions By Bernard I. Comroe, A.B., M.D., instructor in medicine, University of Pennsylvania, senior ward physician, Hospital of the University of Pennsylvania. Second edition, thoroughly revised. 9", cloth, 878 pp., with 242 illustrations. Philadelphia: Lea and Febiger, 1941. \$9.00

A Textbook of Dietetics By L. S. P. Davidson, B.A. (Cantab.), M.D. (Edin.), FRCP (Edin and Lond.), FRSE, professor of medicine and clinical medicine in the University of Edinburgh and physician to the Royal Infirmary, Edinburgh, and Ian A. Anderson, M.B., Ch.B. (Aberd.), clinical tutor and assistant in the metabolic wards, the Royal Infirmary, Aberdeen. With diet sheets constructed by Miss Mary E. Thomson, S.R.N., sister dietitian to the Royal Infirmary, Aberdeen, and a foreword by Sir John Boyd Orr, M.D., D.Sc., LL.D., F.R.S., director, Rowett Institute for Research in Animal Nutrition, Aberdeen. 8", cloth, 324 pp., with 27 tables. New York: Paul B. Hoeber, Incorporated, 1941. \$4.25

Scabies—Civil and Military Its prevalence, prevention and treatment By Reuben Friedman, M.D., assistant professor of dermatology and syphilology, Temple University School of Medicine, Philadelphia. 8", cloth, 288 pp. New York: Froben Press, 1941. \$3.00

Brucellosis (Undulant Fever) Clinical and tuberculous By Harold J. Harris, M.D., health officer, Westport, New York, consulting physician St. Lawrence State Hospital, and attending physician, Elizabethtown Community Hospital. With a foreword by Walter M. Simpson, M.D., director, Kettering Institute for Medical Research, Miami Valley Hospital, Dayton, Ohio. 8", cloth, 286 pp., with 12 colored and 44 black-and-white illustrations. New York: Paul B. Hoeber, Incorporated, 1941. \$5.50

The Medical Aspect of Boring By Ernst Jokl, M.D., head of Department of Physical Education, Witwatersrand Technical College, Johannesburg, South Africa, consultant Medical Aspect of Physical Education, South Africa Defense Force. 8", cloth, 251 pp., with 55 illustrations and 4 plates. Pretoria, South Africa: J. L. Van Schaik, Limited, 1941.

Medical Diagnosis and Symptomatology By Samuel A. Loewenberg, M.D., clinical professor of medicine, Jefferson Medical College, assistant physician, Jefferson Hospital, consulting physician, Philadelphia Hospital for Contagious Diseases and Philadelphia Psychiatric Hospital, and visiting physician, Philadelphia General Hospital and Northern Liberties Hospital. Fifth edition, entirely revised and reset. 4", cloth, 1139 pp., with 520 illustrations. Philadelphia: F. A. Davis Company, 1941. \$12.00

The Doctor Takes a Holiday An autobiographical fragment By Mary McKibbin Harper, M.D. 8", cloth, 349 pp., with 17 illustrations. Cedar Rapids, Iowa: The Torch Press, 1941. \$2.50

Medicine No. 4 in the series Vocational and Professional Monographs By Dwight O'Hara, M.D., professor of preventive medicine and assistant dean, Tufts College Medical School, Boston. 8", paper, 27 pp. Boston: Bellman Publishing Company, Incorporated, 1941. 50c.

Oral Pathology: A histological, roentgenological and clinical study of the diseases of the teeth, jaws and mouth. By Kurt H. Thoma, D.M.D., professor of oral surgery and Charles A. Brackett Professor of Oral Pathology, Harvard University. 4°, cloth, 1306 pp., with 1370 illustrations, including 137 in color. St. Louis: The C. V. Mosby Company, 1941. \$15.00.

The Medical Clinics of North America: New York number, May, 1941. Vol. 25, No. 3. 8°, cloth, 265 pp. Philadelphia: W. B. Saunders Company, 1941. \$3.00.

Mary Fletcher Comes Back: A brief account of the history, progress and future of Vermont's first general hospital. 4°, cloth, 68 pp., with 37 illustrations. Burlington, Vermont: published for the Board of Directors of The Mary Fletcher Hospital, 1941.

Über die Bedeutung der Röntgenuntersuchung für die Kardiologie: Speziell mit Rücksicht auf die Bedeutung der Herzvergrößerung. By Torfinn Denstad. 8°, paper, 80 pp., with 16 illustrations, and 19 tables. Stockholm: P. A. Norstedt und Söner, 1941. Sw. Cr. 8.

BOOK REVIEWS

Manual of the International List of Causes of Death. Based on the fifth decennial revision by the International Commission, Paris, October 3-7, 1938. *Manual of Joint Causes of Death.* Fourth edition, 1939. Prepared under the supervision of Halbert L. Dunn, M.D. 8°, cloth, 452 pp. Washington: United States Government Printing Office, 1940. \$1.25.

These two new editions of standard works, published as a unit, should be of interest to all those engaged in the classification of diseases and in biologic research.

Chemistry and Medicine: Papers presented at the fiftieth anniversary of the founding of the Medical School of the University of Minnesota. Edited by Maurice B. Visscher. 8°, cloth, 296 pp., with 76 figures and 19 tables. Minneapolis: The University of Minnesota Press, 1940. \$4.50.

In formulating an appropriate program for the commemoration of the fiftieth anniversary of the University of Minnesota Medical School, it was decided to focus the scientific program on chemistry as it is related to medicine. The papers thus presented were of such excellence that they were published under the direction of Dr. Maurice Visscher. Fourteen papers, embracing such fields as the application of physical chemistry to medicine, recent investigations in metabolism, aspects of immunity and chemotherapy, and certain approaches to the nervous control of the organism, and including such subjects as heparin and thrombosis, and the chemistry of urinary antiseptics, make this collection of data and well-digested review material by distinguished investigators outstanding in every respect. The book is recommended enthusiastically not only to those in specialized branches of medicine but also to all who are interested in modern medicine. The synthesis of each subject as it is developed is so well done that the collection merits being termed the best symposium book of the year.

The Doctor and the Difficult Child. By William Moodie, M.D. 8°, cloth, 214 pp. New York: The Commonwealth Fund, 1940. \$1.50.

The author treats this subject in a very simple and wholesome manner. He very wisely avoids attempting to lead the physician into the more recently explored psychologic fields, which offer a rare opportunity for many authors to philosophize and speculate on imaginary situa-

tions. The book sticks to the task of thinking "of the patients just as individuals, differing one from another in themselves, their experiences and their setting, and so varying widely in their methods of thinking and acting." Clearly and concisely, the author presents and evaluates the problems of childhood, and then discusses therapeutic measures as they may be applied directly to the child and indirectly toward the environment. Although the book represents the orthodox approach to behavior problems and personality deviations, as carried on in most of the child-guidance clinics, it will have special value for the physician whose practice brings him in contact with the ordinary problems associated with the process of growing up.

The Era Key to the USP XI and NF VI. Fifth edition. Revised by Lyman D. Fonda, professor of pharmacy, Brooklyn College of Pharmacy, Long Island University. 16°, cloth, 320 pp. Newark, N. J.: Haynes and George Company, Incorporated, 1939. \$1.00.

This is the fifth edition of a popular book that has been in existence for forty-six years. It is small and compact in arrangement, and is designed to give the essential information contained in the *United States Pharmacopoeia* and in the *National Formulary*.

As I Remember Him: The biography of R. S. By Hans Zinsser, M.D., S.D. 8°, cloth, 443 pp. Boston: Little, Brown and Company, 1940. \$2.75.

This biography of a physician is essentially an attempt by a representative of the educated middle class to draw a picture of the period of transition between the nineteenth and twentieth centuries. The story, beginning with childhood, is carried through his career as a medical bacteriologist in Serbia, France, Russia, China and Japan, and ends with thoughts on the fact that he would soon be dead.

The style of writing is vigorous, but frequently unconventional and choppy. One finds interesting anecdotes and incisive phrases, such as, "The whole publicizing of culture is a racket." The author attacks those who want education "in hypodermics or like liver extract." In his discussion of the philosophical aspects of life the author finds no hope in achieving a physicochemical basis for human morality, nor does he seek strength in wishful surrender to a religious faith. Despite these mental confusions he acquires a certain degree of philosophical tranquillity and resignation in the last months of his life. Those interested in the history of medicine, as well as others, will find many good things to reflect on in reading this book.

A Textbook of Physiology. By William H. Howell, Ph.D., Sc.D., LL.D. Fourteenth edition, thoroughly revised. 8°, cloth, 1117 pp., with 330 illustrations. Philadelphia and London: W. B. Saunders Company, 1940. \$7.50.

The first issue of this textbook appeared thirty-five years ago. Since that time, the distinguished author has reflected in subsequent editions the spirit and accomplishments of contemporary physiology. The textual material is incorporated under the influence of two guiding principles: the presentation of facts and theories in simple, lucid style, and the exercise of judicious limitations in the selection of such material as has been justified by experiment and observation. Throughout, the author attempts to show that physiology is a living subject, continually undergoing change and adjustment. The short résumés of the literature and the attention paid to works of historical importance enhance the value of the book.

EXPERIENCE WITH ELECTRIC-SHOCK THERAPY IN MENTAL DISEASE*

ABRAHAM MYERSON, MD†

WITH THE ASSISTANCE OF LOUIS FELDMAN, MD,‡ AND ISADORE GREEN, MD§

BOSTON

SINCE the introduction of electric shock for the treatment of mental disorders by Bini¹ and Cerletti and Bini,² a considerable literature has accumulated on the subject. It is true that others³⁻⁵ have used electric shock for producing convulsions and unconsciousness, but to the Italian workers should go the credit for introducing the method as a therapeutic measure in mental disease. The practicability and reasonable safety of their work have been confirmed by Kalinowsky,⁶ Shepley and McGregor,⁷ Wyllie,⁸ Muller,⁹ von Braunmühl,¹⁰ Fox,¹¹ Berkwitz,¹² Kalinowsky and Barrera,¹³ and others.¹⁴⁻²⁶ The authoritative American paper is that of Kalinowsky and Barrera. These workers have given over 10,000 shocks and have clearly outlined the method, the advantages and the disadvantages.

The opinions expressed in the literature on the subject may be summarized as follows. The method is less cumbersome than intravenous medication, especially with resistive patients, and is less costly. The loss of consciousness is instantaneous, and the patient does not remember the treatment, so that he does not have the dread of the method that is so conspicuous in Metrazol shock. There seem, on the whole, to be fewer injuries, such as fracture of the dorsal spine. There is not so much general bodily reaction in the sense of increased pulse rate and blood pressure. The results are at least as good as those in Metrazol shock, with which this method is usually contrasted and from which it developed.

The purpose of the study here presented was fourfold: to test the accuracy of the statements made in the literature; more specifically to evaluate electric-shock treatment in the affective psy-

choses or, more accurately, in the affective disturbances, since in many cases the patients in this study had not reached the psychotic stage; to develop a technique for patient-care or even for home-care so as to avoid hospitalization and commitment, and to build up a technique by which fewer shock treatments would be administered to the patient.

MATERIAL AND METHODS

Thirty-six patients were treated: the diagnosis in 24 being depression or depressed obsessive state, in 9, schizophrenia, and in 3, chronic neurosis (Table 1). The average number of shocks was between five and six. In one case (Case 7), however, fifteen shocks were given in two sets of treatments, following which the patient had a complete remission for a month. He then lapsed back into an agitation, which improved greatly after six additional shocks.

An electrical apparatus, made especially for this purpose by Mr. Frederick T. Davis and one of us (L. F.), is constructed essentially as follows. It has a current source of a 60 cycle, alternating, low-frequency type, with a flexibility and range of control from about 50 to 130 volts and from about 50 to 750 milliamperes. This current is further regulated by means of a variac and a special electronic timing device placed in the circuit for accuracy and safety. Special indicators on the panel are connected with pilot lights, which flash off and on when the current enters the machine and when it is flowing through to the patient. From two terminals on the panel there pass two wires, which are attached by means of insulated clips to the patient's contact electrodes. These metal, non-polarizable contact electrodes are circular in shape and about 5 cm. in diameter. A rubber, self-adjustable headband keeps them in contact with the patient's head in the temporal regions. Before application of the moistened electrodes, the resistance of the skin, a very important factor, is reduced by rubbing a paste containing 20 per

*From the Division of Psychiatry, Research, Boston State Hospital. Aided by grants from the Commonwealth of Massachusetts and the Rockefeller Foundation.

†Professor of neurology (emeritus), Tufts College Medical School; clinical professor of psychiatry, Harvard Medical School; and director of research, Boston State Hospital.

‡Formerly assistant in medicine, Tufts College Medical School; and director of hydrotherapy, Boston State Hospital.

§Now visiting neurologist, Beth Israel Hospital.

cent sodium chloride over each temporal region.

Before treatment was undertaken on human beings, this apparatus was used on rabbits and other animals for a sufficient time to ensure its safety.

By experimentation we learned that in the majority of patients, a voltage of 70 with a milliamperage of 350 to 500 delivered for 0.1 second was sufficient to produce convulsive reactions instantaneously or almost instantaneously. In 2 cases

paratus has worked very reliably, and this assurance is made the more definite by the fact that a dose (that is, voltage and time), once it has been established for a patient, gives a constant response.

One other caution should be mentioned: if the dose selected as a trial is insufficient, at least ten to fifteen minutes should elapse before another is given, since the resistance of the tissues diminishes

TABLE 1. *Summary of Results of Electric-Shock Therapy.*

DIAGNOSIS	CASE NO.	AGE	SEX	NO OF TREATMENTS	PERIOD OF TREATMENT	PLACE OF TREATMENT	RESULTS*
		yr					
Depression or depressed obsessive state	1	40	F	3	3 weeks	Outpatient	Remission
	2	21	M	4	4 weeks	Outpatient	Remission
	3	36	F	4	4 weeks	Outpatient	Marked improvement to remission
	4	23	M	6	6 weeks	Outpatient	Great improvement
	5	33	F	4	3 weeks	Outpatient	Improvement
	6†	62	M	7	3 weeks	Hospital	Remission
	7†	64	M	9	4 weeks	Hospital	
				12	4 weeks	Hospital	Marked improvement after relapse
	8	49	F	3	2 weeks	Hospital	Remission
	9	27	F	7	3 weeks	Hospital	Shift to hypomania, remission
	10	60	M	4	2 weeks	Hospital	Remission
	11	60	M	4	10 days	Hospital	Remission
	12	55	F	3	1 week	Hospital	Remission
	13†	47	F	2	1 week	Hospital	No improvement
	14	48	F	3	1 week	Hospital	Remission
	15	48	F	5	1 week	Outpatient	Improvement
	16	42	F	3	3 days	Outpatient	Remission
	17	41	F	5	10 days	Outpatient	Much improvement
	18	29	M	2	2 days	Outpatient	Much improvement
	19	40	F	4	4 days	Outpatient	No improvement, hospitalized
	20	62	M	5	2 weeks	Outpatient	Improvement
	21	22	F	2	3 days	Outpatient	Remission
	22	33	M	3	1 week	Outpatient	Remission
	23	38	F	4	2 weeks	Outpatient	Remission
	24	55	M	4	10 days	Outpatient	Much improvement
Schizophrenia	25†	48	F	18	6 weeks	Hospital	No improvement
	26	23	M	8	3 weeks	Hospital	No improvement
	27†	35	M	1	1 week	Hospital	No improvement
	28	27	M	9	7 weeks	Hospital	Conduct improvement
	29†	22	M	13	4 weeks	Hospital	Temporary, though not substantial improvement
	30	25	M	6	3 weeks	Hospital	No improvement
	31†	21	M	14	4 weeks	Hospital	No improvement
	32	34	F	9	2 weeks	Hospital	Slight improvement
	33	25	F	6	2 weeks	Outpatient	Conduct improvement
Chronic neurosis	34	33	M	2	5 days	Outpatient	No change refused further treatment
	35	40	F	5	1 long interval	Outpatient	No improvement
	36	31	F	5	4 weeks	Outpatient	Improvement

*The term "remission" is used to indicate the recovery from the particular attack, since it is probably certain that future attacks are not averted by this treatment. By marked improvement is meant social recovery with some residual symptoms.

†These patients had previously received a series of Metrazol shock treatments without resulting improvement.

it was necessary to increase the time to 0.2 second to produce a complete convulsion. The convulsion lasts from thirty to forty-five seconds, which would be the equivalent of the phenomenon designated as "absence 4" by Kalinowsky and Barrera.¹³

The timer should be tested each day and, in fact, before each series of treatments. This can be done by setting the timer at one second and noting whether there is any real discrepancy between it and a split second stop watch. The voltage can be tested out by comparing one voltage indicator with the other. It is of special importance that the apparatus be warmed before each treatment, to make certain that it is running at full capacity, since it slows up definitely after a period of disuse. With these precautions this ap-

markedly after a treatment, and comes back to normal only after such an interval.

RESULTS

The convulsions last from thirty to forty-five seconds, which is about the time of a full Metrazol shock. The dosage, however, can be graded to produce, first, unconsciousness without convulsion and, secondly, unconsciousness with a shorter convulsion. This is a real advantage in those cases in which injury has been sustained and in which it is desirable to continue the treatment without the convulsive reaction.

Our experience confirms the fact that there are few injuries if reasonable precautions are taken, and that the general bodily reaction is not so dis-

turbing as in Metrazol shock, since there is less effect on the pulse rate and the blood pressure. In general, the blood pressure drops for a very short period, and after a few seconds the pulse rate comes back to its normal level. It is also true that the period of apnea is not so long as with Metrazol shock.

There was no injury to the spine of any important consequence. We have not made routine X-ray examination. Two patients complained of backache, in these, X-ray films showed no fracture, and the patient recovered from the backache within ten days. No patient was disabled for any length of time by injury to the back.

Elderly patients with moderate degrees of arthritis changes around the shoulders have complained, after treatment, of considerable pain at the site of the disease. We have found no actual change of any disabling type as a result. This pain has usually disappeared within two weeks.

It is not quite true that patients have no dread of the electric shock method. The patient does not remember the shock itself, and there is a retrograde amnesia for events occurring shortly before and after shock treatment, but the fact remains that in some way or other he was rendered unconscious, and because he learns sooner or later that this was done by electric shock, there is some dread, probably due to the general fear that is associated with being knocked unconscious. However, there is very much less dread than in Metrazol shock because, first of all, the actual treatment causes no pain and, secondly, the loss of consciousness ensues so rapidly that there is not the short agonizing hovering between consciousness and unconsciousness that ushers in the Metrazol convulsion and is usually remembered.

In 3 cases in which Metrazol shock had been tried and in which the administration was exceedingly difficult and consequently ineffective, electric shock produced a convulsion, with good results.

In 1 case in which the presence of coronary thrombosis and cardiovascular disease was proved by electrocardiographic examination and a well established clinical history, electric shock was used despite the general risk. The patient was so agitated and so rapidly impairing his nutrition and general resistance that it was the considered opinion of both the consulting internist and the attending psychiatrist that the treatment offered less risk than the disease. This man received seven electric shocks in three weeks, and had a complete remission. He had been followed closely for ten years, and had had a previous attack that lasted three years, there was every indication that this attack was at least as formidable as the previous one. It

can, we think, safely be assumed that the shock method markedly shortened the attack.

In the following 4 cases, few shocks at relatively long intervals were given.

CASE REPORTS

CASE 1 A 40-year-old woman had had three specific attacks under the observation and treatment of one of us (A.M.) each lasting from 6 months to 2 years. They were characterized by anxiety and depression of severe grade. The patient was given three shocks at intervals of 1 week. She improved after the second treatment. The treatment was discontinued at the end of the third, although she was not completely well. Within a week after the discontinuance of treatment, she was entirely well and has remained well since.

CASE 2 A 21-year-old man (brother of the patient in Case 1), for 3 years had suffered from a moderately depressed state with hypochondriasis, which from time to time became definitely delusional. He believed that his eyes, because of a supposed abnormality, rendered other people nervous and caused them considerable agitation and mental distress so that they would have nothing to do with him. This condition did not yield in the least to psychotherapeutic measures or to drugs such as sedatives, amphetamine sulfate, vitamins and hormones. The patient received four treatments spaced 1 week apart. Since he was still attending school they were given on Saturday mornings at a private house and he went home on Saturday afternoon rested until Sunday noon and went back to school on Monday. At the end of the fourth treatment, the patient was feeling very much better, and there seemed to be a steady progress toward recovery. He no longer has any hypochondriasis; the depression is much improved. There is still, however, a latent feeling of inferiority, which does not seem to handicap him.

CASE 3 A 48-year-old woman was seen during her first depressive attack. This had lasted for a year, and she had made no progress toward recovery. In fact, she was probably worse at the period when treatment was initiated than at any previous time. The first two shocks were given within 3 days. By mischance the electric apparatus was not available for a week, when another shock was given. The fourth shock was to be given after 4 days but since she appeared to be entirely well, in fact somewhat hypomanic, — a very common occurrence after shock treatment of any kind — treatment was discontinued. Since that time the patient has had a mild, though not disturbing exhilaration but has been able to go back to her duties and discharge them perfectly well.

CASE 4 A 60-year-old man was first seen by one of us (A.M.) 8 years previously, at which time he had his first attack of depression. This lasted 8 months, and the patient did not completely recover. He went on, however, fairly adequately, with short attacks from time to time, and 1 month prior to admission entered into a major attack in which he reached the stage of delusion formation, as well as marked depression, with failure in sleep, appetite and the visceral urges generally. His delusions were typical — that great harm was to befall him and his family and that there was a constant barrage of persecutions directed against him because of his misdeeds. He was given four shocks in a period of 2 weeks at which time it was felt advisable to see what would happen without

further treatment, although he did not seem particularly improved. Within a week, however, he was very much better. At the present time he is cheerful, the delusions have disappeared, and there is an amnesia for the whole period of treatment as well as for 1 or 2 weeks of the period of his illness prior to treatment. This man had a slight back injury, from which he recovered entirely in 2 weeks.

Because of the experiences outlined above, we have modified our method of treatment as follows: Those patients who are not too actively psychotic are given outpatient treatment, that is, they go to a private house, which has been prepared for this purpose, receive their treatment, are attended by a nurse for a few hours and then go home. Two or three days are allowed to elapse, after which the patients are again seen; treatment is arranged within the next day or two. After the second treatment, a period of four to seven days is allowed to elapse to see whether improvement is commencing. If this improvement is not apparent, treatment is resumed. If at the end of the third or fourth treatment a favorable upward trend seems to be taking place, no further treatments are given, because we have learned that the recovery process, when once initiated, goes on very rapidly. Thus, in a twenty-three-year-old man (Case 4), who had an obsessive depressive state of at least six years' duration, six treatments scattered over a period of six weeks were sufficient to bring him to the state where the obsessiveness entirely disappeared; he is cheerful and active, and although residual symptoms are present, they are fading away, apparently by some natural process of recovery.

We have treated patients in whom the depressive state has been followed by a manic state that, although it was more comfortable for the patient, was not especially easy to handle. Thus, in a twenty-seven-year-old woman (Case 9), who was depressed for nearly a year, two treatments produced a hypomanic state. Continued treatment of the hypomanic state by the electric-shock method did not seem to do any special good, and it was therefore discontinued. The patient is now in the recovery phase of a manic state. The interesting transition from depression to the manic state while under treatment is significant in showing the biologic relation between the two phases. The mechanism of the transition is entirely unknown, and one can only speculate about its genesis.

Of the 24 patients with depressions or depressed obsessive states, all but 3 showed moderate to marked improvement or had remissions following electric-shock therapy.

Of the 9 cases of schizophrenia treated in this series, none were significantly improved so far as

the essentials of the disease process are concerned. Conduct improved in 3. Delusions became less conspicuous. However, the retreat and the incapacity to meet the situations in life were only transitorily changed for the better. There is little evidence that either Metrazol or electric-shock therapy is of fundamental importance in schizophrenia except in relation to some of the catatonic states.

Three cases of neuroses of severe grade were treated. One of these patients was unwilling to continue the treatment after two shocks, because of the unpleasant failure of memory that manifests itself in almost all cases for a short time after shock therapy. The other 2 patients are still under treatment with results that are doubtful. These cases, however, had also resisted other forms of treatment.

SUMMARY AND CONCLUSIONS

Electric-shock therapy seems to be without appreciable danger. It is not recommended in cases of heart disease or hypertension except when there seems, on the whole, to be nothing to lose—that is, when the mental condition is desperate and threatens the life of the patient. In our cases no harm has followed. In one case of definite cardiac disease and in one of distinct hypertension, electric-shock therapy was of great value.

Although no shock therapy can be classed as pleasant, electric-shock therapy is the least disturbing to the patient and creates less fear and resistance to the treatment. It is also more expeditious and can be used in cases in which it is inadvisable to give Metrazol.

It is possible to use this treatment without hospitalization and by what we call the "outpatient method." There is no reason why it should not be used in the patient's own home with sufficient nursing attendance.

The psychoses of choice for treatment are the marked, continuous depressions. The value of the treatment in the hypomanic state is less certain. It has the same general value as Metrazol in the treatment of schizophrenia: a limited but useful value from the standpoint of control of the patient. It is too drastic a method to be used in the neuroses except in the chronic, obsessive and depressive types.

There is a disturbance of memory in many cases for some time after the treatment. This does not seem to be permanent or final. No neurologic sequelae of any kind have been observed in our patients.

It is probably of great advantage to give as few treatments as possible, to wait between treatments to see what progress is being made, and to allow

as much progress as possible to take place without further therapy. In other words, it may be necessary to give only three or four treatments for a complete remission to occur in a depressive state.

It appears that the shock therapy, especially electric-shock therapy, is of unequalled value in the treatment of the depressive mental states.

TULAREMIA IN IMPORTED RABBITS IN MASSACHUSETTS*

DAVID L. BELDING, M.D.,† and BEULAH MERRILL, B.A.‡

BOSTON

IN recent years it has been the practice of various Massachusetts game clubs to stock their covers with cottontail rabbits imported from states west of the Mississippi River. On April 25, 1940, we were able to demonstrate the presence of tularemia in a rabbit imported from Missouri. The finding of a second diseased rabbit on November 16, 1940, this time from Arkansas, confirmed the fact that rabbits infected with tularemia are being introduced into Massachusetts. The importance of tularemia, its rapid spread among wild mammals, its ready transmission from animals to man, and the occurrence of three endemic human infections in Falmouth since 1937 warrant bringing these findings to the attention of Massachusetts physicians.

TULAREMIA

Tularemia, a disease of lower animals and man, is caused by a plaguelike bacterium, *Pasteurella tularensis*. The disease in man is characterized by the rapid onset of typhoidal symptoms and the associated development of an ulcerating lesion with local adenitis at the site of infection. The mortality rate is about 5 per cent.

Incidence in man. Since 1919, human infections have been recognized in forty-eight states and the District of Columbia, and since 1925, in ten foreign countries. The number of reported cases and deaths appears to be increasing. Up to

1924, only 15 cases had been reported. From 1924 to 1935, a total of 6206 cases occurred in the United States with 299 deaths, the highest incidence being in Illinois, Ohio and Virginia. In 1938, 2088 cases with 139 deaths were reported, and in 1939, 2200 cases with approximately 150 deaths.¹

New England has been comparatively free from the disease, a total of 8 human cases having been reported: Maine, 1; Vermont, 0; New Hampshire, 1; Connecticut, 1; Rhode Island, 1; and Massachusetts, 4. The 4 Massachusetts cases included a man infected from a refrigerated rabbit shipped from Illinois in 1930 (no epidemiologic significance as an imported market rabbit)²; a ten-year-old girl at Falmouth in 1937 (evidently infected by a dog, which presumably had acquired the infection from rabbits)³; a six-year-old girl at Falmouth, bitten by a tick in 1938⁴; and a woman at Falmouth, bitten by a tick in 1939.⁵

Incidence in animals. The disease has been observed in a variety of animals. Human infection has been traced to twenty-four forms of wild life, though wild rabbits and hares account for over 90 per cent of infections in man. The hosts include wild rodents, other wild mammals, domestic mammals and game birds.

Transmission. Most human infections are acquired in handling diseased animals, chiefly rabbits, the organisms entering the body through wounds, superficial abrasions or the conjunctiva, usually during the skinning, dressing or dissection of the animal. Thus marketmen, hunters and housewives who dress rabbits become in-

fected. The dissection of infected animals has caused 56 cases of infection in laboratory workers. Miscellaneous infections have been reported from the dressing of or from the bites of other animals. The eating of insufficiently cooked wild-rabbit meat has caused 20 cases, and water-borne epidemics have been reported in man in Russia and in beavers in Montana.¹

The organism may also be transmitted from animals to man by the bites of insects. The Rocky Mountain wood tick (*Dermacentor andersoni*) has caused 53 human cases in Montana and surrounding states; the American dog tick (*D. variabilis*), 73, principally in the southern states; the deer fly (*Chrysops discalis*), 68 in Utah and neighboring states; and undetermined species of insects, 9. The rabbit tick (*Haemaphysalis leporis-palustris*) is the chief factor in the transmission of the disease from rabbit to rabbit.

IMPORTED RABBITS

During the last two years, 219 rabbits imported by Massachusetts game clubs have been examined at our laboratories at the request of the Division of Fisheries and Game of the Massachusetts Department of Conservation. Post-mortem conditions permitted complete examination of only 136. These rabbits either died in transit or shortly after arrival in Massachusetts. In this series, previous to the discovery of the first rabbit with tularemia, 109 rabbits had been examined, with negative results. In the interval between the finding of the first and the second infected rabbit, 24 others showed no signs of tularemia. Also, no evidence of tularemia was found in a previous series of 194 imported rabbits examined in 1937. The presence of tularemia in 2 out of 330 rabbits, or 0.6 per cent, corresponds closely with the usually accepted incidence of 1 per cent infection among wild rabbits.

The existence of tularemia was demonstrated by the detection of lesions in the liver and spleen, by the production of the disease in guinea pigs, and by the isolation of the causative organism, *Pasteurella tularensis*. Our findings were verified from the original material by Dr. Edward Francis, of the National Institute of Health, United States Public Health Service, who obtained further confirmation by agglutinating the organism with known tularemic serum.

From 1937 to 1940, 24,689 imported western rabbits (24,474 cottontails and 215 jacks) were liberated in Massachusetts. Of these 7091, or 28.7 per cent, were released in the tick-infested counties of southeastern Massachusetts (Barnstable 1807, Bristol 3329, Dukes 142, Nantucket 340 and Plymouth 1473). The two tularemic rabbits were

found in the following shipments: 51 rabbits (9 dead) from Rutledge, Knox County, Missouri, received by the Rockdale Rod and Gun Club, of Northbridge, in April, and 84 rabbits (25 dead) from Berryville, Arkansas, received by the Weymouth Sportsmen's Club in November.

DISCUSSION

The imported rabbits are admitted to Massachusetts under certification by the accredited health authorities at the shipping sources. The certificates state that there has been no epidemic of tularemia or rabbit fever in the last two years in the counties in which the rabbits are trapped, and that these counties are free from contagious and infectious rabbit diseases. The presence of tularemia in certified rabbits from two states indicates that such guarantees are inadequate to prevent the inclusion of tularemic rabbits in these shipments. Since tularemia exists in practically all states exporting rabbits, the best safeguard against its introduction into Massachusetts is the enactment of legislation prohibiting the importation of rabbits. Such legislation has been enacted by at least three states—Connecticut, New Hampshire and Ohio.

Not all infected rabbits die during shipment. Those recently infested with diseased rabbit ticks or possibly infected by close contact with diseased rabbits before and during shipment may be liberated. It is fair to assume that tularemia has been present in a fraction of 1 per cent of the 24,689 rabbits so far liberated. Since the disease is transmitted from rabbit to rabbit by the rabbit tick, it is likely to spread among the native rabbits and also among other wild mammals and birds, thus endangering the supply of indigenous rabbits and wild game.

The American dog tick, *D. variabilis*, a known vector, is abundant in southeastern Massachusetts, south of Plymouth and east of Marion. The larvae and nymphs feed on small rodents, particularly field mice, and the adults on larger mammals and man. Thus this tick is capable of transmitting tularemia to both animals and man, since infection acquired by the larva or nymph persists in the adult and may even be transmitted to subsequent generations. A widespread infection among these ticks would result not only in damage to game animals but also in danger to man, since, although tularemia is most frequently acquired through contact with diseased rabbits, it is also transmitted by infected ticks.

The 3 cases of human infection reported from Falmouth since 1937, 2 from bites of ticks, indicate the presence of tularemia in the wild animals and ticks of that region. It is an interesting

coincidence that these endemic human cases developed after imported rabbits were first liberated in 1937. The establishment of other endemic foci in native wild animals from imported rabbits appears inevitable, and additional cases of human infection are to be expected in tick infested areas

SUMMARY AND CONCLUSIONS

The presence of tularemia has been demonstrated for the first time in imported rabbits liberated by Massachusetts game clubs. Infected rabbits have been found in shipments from Missouri and Arkansas.

Certification at the shipping source that these rabbits are from tularemia free districts does not guarantee freedom from this disease.

The importation of tularemic rabbits threatens to establish endemic foci in native rabbits and

other wild game that may ultimately reduce the wild life population.

Since 1937, 24,689 imported rabbits have been liberated in Massachusetts. The first three endemic cases of human tularemia in this state have been reported since 1937.

In the interests of public health the further importation of rabbits should be prohibited by legislation, even though an endemic focus of tularemia appears to have been established.

HEALED STAGE OF PERIARTERITIS NODOSA*

Report of a Case

ELTON R. BLAISDELL, M.D.,† AND JOSEPH E. PORTER, M.D.‡

PORTLAND, MAINE

PERIARTERITIS nodosa is characterized by a multiplicity of clinical and laboratory features. The symptomatology in any one case depends on the stage of the disease and the organ predominantly involved. In general, however, most cases manifest a strong allergic tendency. This syndrome was first described by Kussmaul and Maier¹ in 1866, and since that time numerous isolated cases have been reported in the literature; the etiology is still obscure, however, and the primary locus of origin of the process in the arteries is not settled. Rackemann² reviewed 245 cases in the literature, and found asthma in less than 10 per cent, and high eosinophilia—over 25 per cent—in about 14 per cent. He stated that there is insufficient evidence at present to say that periarteritis nodosa is an allergic disease. Cohen, Kline and Young,³ Swift, Derick and Hitchcock⁴ and Harvey⁵ favor an allergic or hyperergic basis for the disease. Because the disease is not confined to the adventitia of the vessels, Dickson⁶ has appropriately changed the name to "polyarteritis nodosa."

The classification devised in 1930 by Arkin⁷ is interesting. He divided the disease into four dif-

ferent stages, based on the histologic structure of the transformations in the arteries. He included in his series a "healed granulation tissue stage," with a report of one case. In this case, the histologic changes, which were considered characteristic, were intimal proliferation, with new formation of elastic fibrils, leading to stenosis or even complete occlusion; extensive destruction of the media, including the elastica interna, or of the entire vessel wall, with aneurysm formation and thrombosis—the thrombosis was followed by complete organization, with occasional deposition of hemosiderin; a periarterial healed granulation tissue mantle, consisting of dense fibrous connective tissue containing capillaries and hemosiderin deposits, extensive destruction, with even aneurysm formation, in arteries, as well as high grade intimal proliferation; healed infarct scars in most organs. This case presented the clinical picture of cardiac insufficiency and renal insufficiency.

In 1939 Weir⁸ reported a case of polyarteritis nodosa in which all stages of the disease, from the earliest acute to healed lesions, were present at the time of death.

CASE REPORT

H M, a 49-year-old carpenter, was admitted to the Maine General Hospital on October 28 1937. He stated

*From the Department of Medicine and the Department of Pathology Maine General Hospital, Portland.

†Associate chief Medical Service Maine General Hospital.

‡Associate pathologist Maine General Hospital.

that he had always been well until December, 1936, when he had influenza. He became afebrile within a few days, but developed a wheezy cough, which persisted until the following June. During the summer months he worked at his trade. Four weeks before admission to the hospital the cough reappeared, and he started to lose weight. A physician made a diagnosis of asthma. After failing to respond to treatment at home, he was admitted to the hospital.

On examination, the patient was sitting upright in bed, with slightly labored wheezy respirations. The temperature was normal. The pupils and fundi were normal. There was no nasal obstruction. No skin lesions were seen. The heart rate was 110 and regular. There was no cardiac enlargement, and there were no murmurs. The blood pressure was 140/90. The radial arteries apparently were not sclerosed, and the pulsations in both dorsalis pedis vessels were good. Chest examination showed limited expansion, many musical rales and prolonged expiration. The urine had a specific gravity of 1.018, with 40 mg. of albumin per 100 cc. and no casts. Examination of the blood revealed a red-cell count of 4,400,000 with a hemoglobin of 90 per cent, and a white-cell count of 39,500 with 55 per cent neutrophils, 32 per cent eosinophils and 13 per cent lymphocytes. The blood Kahn and Hinton reactions were negative. Skin tests for foods and pollens were unsatisfactory, since the patient reacted to all. The Bachman skin test for trichinosis was negative.

The symptoms and chest findings remained the same during the next 3 weeks. Partial temporary relief was obtained with adrenalin. A vesicular eruption appeared on the forehead and extremities. This was thought to be due to iodides, which had been given for cough, and gradually disappeared after the iodides were discontinued. A white-cell count on November 4 was 43,600, with 73 per cent eosinophils. On November 25, the patient complained of pain in the left axilla. Two days later, very few signs of asthma could be heard, but there were many moist rales over the left base, with a decrease in the percussion note. The sputum showed no pneumococci. The temperature, which had been normal, rose to 103°F. X-ray examination showed increased density in the left base. The white-cell count was 34,000, with 65 per cent eosinophils. The temperature continued from 99.5 to 102°F. The cough became more productive, and on December 16 x-ray study still showed increased density at the left base. A small lung abscess was considered probable, and postural drainage increased the sputum output. The white-cell count fell to 12,000, with only 3 per cent eosinophils. The productive cough continued, but the patient was able to eat a regular diet, in spite of an afternoon temperature of 100°F, which persisted until 10 days before discharge. On January 21, 1938, the left lower-stem bronchus was injected with lipiodol. There was considerable puddling of the oil in an area just above the left diaphragm and behind the left border of the heart. The bronchi in this area were apparently dilated, leading to the conclusion that this represented a bronchiectasis. The patient, at that time, was comparatively free of asthma, which had been so troublesome during the 1st month of hospitalization. Postural drainage was continued. The amount of sputum, which at one time measured 290 cc. daily, gradually decreased, and at the time of discharge on February 15, it was about 30 cc. daily. There was an apparent increase in weight, although the patient was not weighed. The red-cell count was 4,100,000 with a hemoglobin of 68 per cent, and the white-cell count was 12,400 with 72 per cent neutrophils, 3 per cent eosinophils and 25 per cent

lymphocytes. Examination of the urine showed a specific gravity of 1.012 (before breakfast), 5 mg. of albumin per 100 cc., no sugar, a few hyaline casts and 6 to 8 red cells per high-power field. The patient was discharged with final diagnoses of bronchial asthma, bronchopneumonia, lung abscess and bronchiectasis. However, in reviewing the case at the following monthly medical-staff meeting, periarteritis nodosa was considered to be a strong probability.

The patient was readmitted on November 27, 1938. He stated that he had had a "fairly comfortable" summer, but that for the previous month two or three mild asthmatic attacks had occurred daily. They were easily controlled with inhalations of a 1:100 solution of adrenalin chloride. His acute illness had begun 1 week before admission, during which time frequent hypodermic injections of a 1:1000 solution of adrenalin chloride were necessary to control the asthma.

The appearance of the patient on admission was essentially the same as that on his first admission. The temperature was 103°F. The chest was full of musical rales. There was no dullness on percussion. X-ray examination revealed irregular rectangular masses in the mid-hilus regions, with extension outward toward the periphery on both sides. Opinion was reserved by the roentgenologist. The white-cell count was 31,600, with 31 per cent eosinophils. Urine examination showed 400 mg. of albumin per 100 cc., with many hyaline and granular casts, and 10 to 20 red blood cells per high-power field. The blood pressure was 148/90. The cardiac rhythm was regular, and the rate was 110. A small piece of pectoralis major muscle removed for examination failed to show evidence of vascular disease. A bone-marrow biopsy showed 41 per cent eosinophils, with an otherwise normal smear.

The temperature gradually returned to normal at the end of 3 weeks. The asthmatic attacks decreased in number and in severity, and with the disappearance of the fever, further medication for this condition was not necessary. However, the urine still contained a large amount of albumin, with both hyaline and granular casts and numerous red blood cells. The blood urea nitrogen remained normal. Examination of the blood showed a red-cell count of 3,130,000 with a hemoglobin of 58 per cent, and a white-cell count of 27,400 with 43 per cent neutrophils, 45 per cent eosinophils, and 12 per cent lymphocytes. The chest was clear except for a decrease in breath sounds over a small area in the left base. Following an afebrile period of a week, the patient was extremely desirous of going home, and was discharged on December 24 with a diagnosis of probable periarteritis nodosa.

A third admission occurred on April 10, 1939, when the patient was admitted to the Surgical Service. Following the last period of hospitalization, he had been in comparative good health and had required no medication for asthma. During the previous winter, a small, easily reducible right inguinal hernia had appeared. During the 3 days before entry he had been unable to reduce the hernia, and his bowels had not moved. On the morning of admission, the vomitus was said to have been fecal in character. Operation was performed immediately under spinal anesthesia. The surgical records show that the operation was performed without difficulty, and that the bowel was not gangrenous. Twelve hours later the temperature was 104°F. There was very little cough, and chest examination was essentially negative. From a small amount of sputum, which was all that could be obtained, a Type 2 pneumococcus was cultured. Although x-ray films taken with a portable machine failed to show con-

solidation, sulfapyridine was given, and the temperature returned to normal at the end of 48 hours. Examination of the blood revealed a hemoglobin of 65 per cent, and a white-cell count of 14,800, with only 2 per cent eosinophils. The urine still contained a large amount of albumin, with both hyaline and granular casts and red blood cells. The blood pressure was 120/80. The patient was discharged by the Surgical Service with a diagnosis of strangulated right inguinal hernia.

The patient was admitted for the fourth and last time on May 8, 1940. During the previous summer he had gained 15 pounds in weight, and had been able to work at his trade for 6 weeks. In January, a cold was contracted. This was followed by a 2 months attack of asthma, which was controlled by inhalations of a 1:100 solution of adrenalin chloride. The asthma ceased rather abruptly, but the patient's strength did not return. Instead, there was increasing weakness with dyspnea not accompanied by wheeziness. The family noticed an increasing pallor. The bowels were looser than usual, and there was nocturia, three to five times a night. Nausea had been present most of the time during the previous month.

The clinical picture was that of chronic renal insufficiency with impending uremia. Air hunger was evident. Cyanosis was not present. There was a distinct pallor of the skin and mucous membranes. The face was slightly puffy. There was no other evidence of peripheral edema. Many moist rales were heard over both lung bases. Asthma was not present. The temperature was 99°F. The heart rate was 100 and regular. The blood pressure was 164/88. The liver edge was thought to be three fingerbreadths below the right costal margin. The spleen could not be felt. The urine examination showed a specific gravity of 1.010, with 200 mg of albumin per 100 cc and both hyaline and granular casts and red blood cells in the sediment. The blood urea nitrogen was 115 mg. The red-cell count was 1,900,000 with a hemoglobin of 30 per cent, and the white-cell count 10,800 with 83 per cent neutrophils, 2 per cent eosinophils and 15 per cent lymphocytes. Pulmonary edema gradually increased, in spite of an attempt at parenteral digitalization, and death occurred 6 days after admission.

Autopsy. The heart was slightly hypertrophied, weighing 400 gm. The right lung weighed 725 gm, and the left 525 gm, and there was congestion and atelectasis of the more dependent portions. The spleen weighed 210 gm, the tissue was firm, and there was a distinct subcapsular zone of gray tissue 3 mm thick, the pulp was dark red and contained an occasional gray firm focus up to 8 mm in diameter, resembling a tubercle. The liver weighed 1875 gm and, except for a scarred subcapsular focus 0.5 cm in diameter, was not remarkable. There was congestion of the gastric mucosa. In the first portion of the duodenum an area 1 cm in diameter in the mucosa was granular, and the wall thin. The remainder of the gastrointestinal tract merely showed congestion of the mucosa. The right kidney weighed 75 gm, and the left 90 gm. The capsules stripped with difficulty, to reveal a pale yellow gray, finely granular surface, with occasional elevated coarse granules. The cortex varied from 2 to 4 mm in thickness. The pelves and calyces were not dilated. A few scattered atheromatous deposits were present in the aorta. The brain weighed 1300 gm and was essentially normal.

Microscopic examination reveals lesions in the small

and medium sized arteries of the duodenum, spleen, kidneys, heart and lungs that are characteristic of the healed end stage or scar tissue stage of periarteritis nodosa, as described by Arkin.⁷ The involved vessels are either completely or almost completely replaced by dense scar tissue, with marked narrowing or absence of lumens (Fig 1). As a result of this process in the kidney, practically all the glomeruli are sclerosed. In only one vessel of all the tissues studied is there any evidence of activity. That is in the kidney, where one medium sized artery shows occlusion of the lumen by scar tissue, in which fibrin and leukocytes are scattered through the wall, with a perivascular lymphocytic and polynuclear infiltrate.

This patient died of renal failure and uremia, resulting from a healed arterial and arteriolar process in the kidneys.

In the case described above, the lesions in the vessels of the spleen, kidneys, duodenum, lungs and heart were all healed and were characterized

FIGURE 1 Low Power Photograph of One of the Occluded Arteries in the Spleen

by collagenous thickening of the vessel walls to the extent that in the spleen and kidneys many of the lumens were completely occluded, occasionally there were hemosiderin deposits and periarterial lymphocytic infiltrations. In only one vessel in all the sections studied was there any evidence of activity in or about the vessels.

In this single case, we are unable to say in which coat of the vessels the disease began, or what the etiologic factor was, but the presence of fever, leukocytosis, eosinophilia and asthma is in favor of an inflammatory process, possibly on a hyperergic basis. Clinically there were periods when the patient was symptom free, a fact that suggests some resistance to the allergic stimulus. The vascular processes did heal, but by their very nature resulted, especially in the kidney, in an ischemic process that, once initiated, was progressive and not reversible. In such cases, the more

completely healed and fibrotic the vessels become, the more occlusion takes place, with ischemic necrosis occurring in structures dependent on these vessels for blood supply.

SUMMARY

A case of periarteritis nodosa is presented in which the vascular lesions were healed at the time of death.

The cause of death was renal insufficiency.

ORTHOPEDICS IN NEW HAMPSHIRE*

EZRA A. JONES, M.D.

MANCHESTER, NEW HAMPSHIRE

THIS meeting is of historic importance to the New Hampshire Medical Society, and because of this, I feel it is of interest at the present time, and probably will be in the future, to record the history of organized orthopedics in New Hampshire during the last quarter century, especially as it relates to crippled children. Moreover, the president of this society is expected to make an annual address, and unfortunately the election to this position does not invest me with oratorical or oracular powers. Therefore, I should like to talk about orthopedics, because that is the only work I have done for the past twenty-five years.

Although something has always been accomplished in this state for the relief of crippled children, orthopedic surgery itself, one of the newer specialties of medicine, did not attract many to it until after World War I. In 1923 in the United States there were 327 surgeons who devoted their time exclusively to orthopedics, in 1940 there were 1077. But even before this country entered World War I, New Hampshire was organizing for orthopedic work.

In 1914 the District Nursing Association of Manchester, an organization supported by private subscriptions, began holding clinics every two weeks in a room on Lake Avenue here in Manchester. In the beginning, the patients were referred to the clinic by local physicians and city nurses, but later, physicians in surrounding communities began sending their patients there. Dr. W. Russell MacAusland, of Boston, came up every fortnight to super-

vised the orthopedic work. Growth of interest was constant.

In 1925 the records show that 1200 patients, representing twenty-six towns in this state, had visited the clinic. At that time there were no funds for hospitalization. But later the State did appropriate \$2500 for braces. Some money also was received from various societies. In this connection I want to emphasize the philanthropy of the service clubs in supplying funds and the generosity of the hospitals in providing free beds. In that period, so meager were our physical resources, it was necessary to do manipulations and plaster work at the district-nursing rooms. We have gone a long way since then, both in financing methods and in clinic facilities.

There also is value in noting the type of cases that came to the clinic in those early years. Most of them were of long standing, with marked contractions and deformities. It will be recalled that infantile paralysis was prevalent at that time, and seemed to be of a type more virulent than at present—that is, more muscle groups were involved than in the cases we are seeing now. As time has gone on, these cases have been recognized earlier, and deformities, because of prompt treatment, are therefore less marked.

Next in number to infantile-paralysis cases, came those of tuberculous bone and joint disease. In the period of which I speak, patients came to the clinic with marked bone destruction, and in the spinal cases, kyphosis was nearly always present. Today, owing to improved hygienic conditions, bone tuberculosis is rather infrequent, and its early recognition

*Presidential address delivered at the annual banquet of the New Hampshire Medical Society, Manchester, May 14, 1941.

makes treatment possible before deformities occur. This also is true of the deformities caused by rickets. In 1920, operations for bowlegs were performed frequently. Today, thanks to our better knowledge of diet, an osteotomy for bowlegs is rarely done.

Another decrease is noted in birth injuries, especially obstetric paralysis of the arm. In the first eight years, we had 24 cases of obstetric paralysis, in the last fifteen years, there have been only 18. This is, of course, due to improved obstetric technique, and shows the effect of medical advance over twenty five years.

Tremendous benefit also has resulted from the interest of laymen. An outstanding instance is the part so willingly played by the Rotary Club of Nashua. In 1921 this club sponsored a weekly crippled children's clinic, which has continued ever since. It has been of immeasurable benefit not only in Nashua, but in the towns of the southern part of the State. Its record of achievement indicates that 1124 patients have been treated at the clinic since 1921; and that twenty-eight towns have taken advantage of the facilities available. Interest in this work grew until in 1939 a building was erected that serves both as rooms for the weekly clinic and as headquarters for the New Hampshire Crippled Children's Society. In addition, the Rotary Club of Keene has practically underwritten the work that is done for crippled children in Cheshire County.

Mention of the New Hampshire Crippled Children's Society prompts me to say that the work in behalf of these youngsters had its greatest impetus in 1936, when this society was formed. This is a branch of the International Crippled Children's Society, and was founded by men and women who had been interested in the work in New Hampshire for many years. Easter Seals, generously purchased by the public, provide a measure of the necessary funds. Other money is received from private contributions. Approximately \$12,000 is available from these two sources. Additional funds became available in 1937 when the society brought to the attention of the legislature the need of more funds for the work among crippled children. The legislature was prompt to appropriate \$11,000 to the State Board of Health, the money to be used among the crippled children of the State. That sum was matched by the federal government, thus bringing the amount available from the State Board of Health to \$22,000. This year Governor Blood has raised the appropriation in his health budget. This will render further help.

I want to speak, too, of the President's Ball Fund for Infantile Paralysis, which has raised about \$6000. This sum is handled by a special

made up in part by members of the New Hampshire Crippled Children's Society and of the State Board of Health.

The arrangements of these three groups—the President's Ball Fund, the New Hampshire Crippled Children's Society and the State Board of Health—are such that there is very little duplication of work. The fund of the State Board of Health is under federal regulation and designates the type of case and the age of the patient to be treated, the age limit being twenty-one. The President's Ball Fund is used for infantile paralysis only, but there is no age limit. Neither of these two organizations can supply transportation either to or from clinics or hospitals. However, the New Hampshire Crippled Children's Society is able to use its funds in any way the board sees fit, and therefore supplies the aid the other two groups cannot. Thus, thanks to the collaboration of the three organizations, coordinated aid to all types and all ages of cripples is made possible.

Since the organization of these three groups, regular clinics have been established, and two state nurses, especially trained in orthopedic work, are available. Clinics are held in Manchester and Nashua every week, in Concord every five weeks, in Laconia every two months and in Littleton every three months. At these clinics, examinations are made, records are kept, and some treatments are given. State nurses attend all clinics, do follow-up work at patients' homes and see that the patients are returned to the clinic nearest their homes for observation at the proper time, or to hospitals for operation.

The average attendance at these clinics is about 30, but the high number at any one has been 57 patients. Since the start of the state work and up to May 1 of this year, 1878 patients under twenty-one have been treated or are under treatment. This number, together with the approximately 600 patients who are not on the state-board records, show, I believe, that New Hampshire, taking into consideration the comparatively small amount of funds available, is doing a class of work among crippled children that is not exceeded by any other state.

These results have only been made possible by the many doctors, nurses and laymen who have been interested in the work. I wish it were possible for me to be specific and name all those who have contributed their support to this program. This cannot be done, however, but they all have the satisfaction of knowing that efficient work has been effected and that machinery has been organized which will carry on this work for long years to come.

Elm Street

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Annual Meeting, May 21 and 22, 1941

THE annual meeting of the Council of the Massachusetts Medical Society was called to order at 10:30 a.m. in the Swiss Room of The Copley-Plaza, Boston, on Wednesday, May 21, by the president, Dr. Walter G. Phippen, Essex South; 263 councilors were present (Appendix No. 1).

The records of the special meeting of April 9, 1941, as published in the May 8, 1941, issue of the *New England Journal of Medicine* were presented by the Secretary *pro tempore* and approved by the Council.

The following nominating councilors answered to the roll call by the Secretary *pro tempore*: W. D. Kinney, Barnstable; P. J. Sullivan, Berkshire; W. H. Allen, Bristol North; E. F. Cody, Bristol South; F. W. Snow, Essex North; F. J. Barnard, Franklin; A. G. Rice, Hampden; W. J. Collins, Hampshire; R. R. Stratton, Middlesex East; Dwight O'Hara, Middlesex South; D. D. Scannell, Norfolk; W. G. Curtis, Norfolk South; W. H. Pulsifer, Plymouth; W. B. Breed, Suffolk; R. P. Watkins, Worcester; and B. P. Sweeney, Worcester North. No nominating councilors or alternates from the Essex South and Middlesex North districts responded.

Dr. J. Harper Blaisdell, Middlesex East, made the following motion:

That if and when we adjourn it be until Thursday, May 22, at the end of the Annual Discourse, which follows the annual meeting of the Society.

Dr. Phippen explained that the motion was necessitated because of the proposed changes in the by-laws creating the position of president-elect, since this officer could not be elected until after the changes had been adopted at the annual meeting of the Society. The motion was seconded by Dr. Charles E. Mongan, Middlesex South, and was passed by unanimous vote.

The nominating councilors then retired.

REPORTS OF STANDING COMMITTEES

State and National Legislation

The chairman, Dr. Henry C. Marble, Suffolk, presented an informal report.

Dr. Marble spoke of the bill specifying that the requirements for admission to the practice of medicine in Massachusetts be the same as those of the National Board of Medical Examiners. This bill was approved by the Society and opposed by the

secretary of the Board of Registration in Medicine; it was given "leave to withdraw."

He then said that the bill requiring that barbiturates be only sold on prescription, which was approved by the Society but opposed by the druggists' lobby, was defeated; and added that the bills concerning premarital examination, which were, in general, approved by the Society, were still in committee.

He added that the bill to place a medical officer in the Department of Industrial Accidents, which was approved by the Society and opposed by the American Legion and the American Federation of Labor, was dropped.

The bill permitting the creation of a medical-service corporation, sponsored by the Society, was reported by Dr. Marble to have been approved by the lower body of the Legislature and awaited approval by the Senate.

He stated that the bill petitioning a separate board of registration for the osteopaths had been withdrawn, and that those asking for a postponement of the effective date of the Approving Authority had also been withdrawn.

In regard to the bill sponsored by the Nurses' Association to create a separate board to control various nursing activities, Dr. Marble said that the committee had agreed with certain hospital authorities that such a board should be under the advisory control of a supervisory board, composed chiefly of physicians. This suggestion, however, was not incorporated in the bill as presented. He stated that the committee had been told that the bill had been entirely rewritten in the legislative committee.

Dr. Marble said that the perennial antivaccination bill had been given "leave to withdraw."

The bill to prohibit the sale of ethyl alcohol except on prescription was favored, but strongly opposed by the druggists' lobby, and defeated 110 to 87. Likewise, the committee's efforts to support the antifireworks' bill were of no avail.

Dr. Marble concluded by stating that all efforts of the committee had been of the nature of "sniping" and that it seemed to him that, in the future, the Society should take the initiative on legislative matters pertaining to medical care.

It was moved that the report be accepted, but Dr. Mongan brought out the point that, according to the by-laws, the report of a standing com-

mittee should be an official report by the committee rather than an informal report by the chairman. During the discussion that followed Dr Marble acknowledged that the report as given had not been signed by the members of his committee. Dr Mongan moved that the report be tabled until such a time as the committee made a written report. The motion was seconded, and eventually carried, 96 to 90.

Dr. Charles C Lund, Suffolk, moved that Dr Marble and his committee be thanked for their efforts and for their informational report of progress. This was seconded. After some discussion, the motion was passed.

Membership

The report (Appendix No 2) was presented by the chairman, Dr. G Colket Caner, Suffolk. It was approved by the Council.

Ethics and Discipline

The chairman, Dr Robert L DeNormandie, Suffolk, presented the report (Appendix No 3), which was accepted by the Council.

Medical Education and Medical Diplomas

The report (Appendix No. 4), presented by the chairman, Dr John P. Monks, Suffolk, was accepted by the Council.

Public Health

The chairman, Dr Francis P. Denny, Norfolk, presented the report (Appendix No 5), which was approved by the Council. He then moved that the Society adopt the resolution contained in the report of the committee; this was seconded and so voted.

Medical Defense

The report (Appendix No 6), presented by the chairman, Dr Arthur W. Allen, Suffolk, was accepted.

Arrangements

The report (Appendix No 7) was read by the Secretary *pro tempore* and was accepted.

Others

There were no reports from the Committee on Financial Planning and Budget, Committee on Permanent Home and Committee on Publications.

REPORTS OF SPECIAL COMMITTEES

Public Relations

The secretary, Dr Elmer S Bagnall, Essex North, presented the report (Appendix No 8), which was accepted, together with the recommendations.

Postgraduate Instruction

The report (Appendix No 9), copies of which had been distributed to all members of the Council, was referred to by the chairman, Dr. Frank R Ober, Suffolk. He called attention to the need for all members of the Society to co-operate to guarantee the success of the New England Postgraduate Assembly. The report was accepted.

Physical Therapy

The chairman, Dr Franklin P Lowry, Middlesex South, stated that there was no formal report but that the committee desired to call attention to the fact that a clinic of physical therapy had been established at the Massachusetts General Hospital and that the director, Dr. Watkins, had been made an assistant professor of medicine at the Harvard Medical School. The committee hopes, he added, that this will serve to lay a broad foundation for the future of physical therapy. The informal report was accepted.

Expert Testimony

The chairman, Dr George L Schadt, Hampden, reported that some progress had been made but that no formal report was warranted. The President declared that the report would be considered as accepted.

Industrial Health

The report (Appendix No 10) was presented by the chairman, Dr W Irving Clark, Worcester, and was accepted.

Army Medical Library and Museum

The report (Appendix No 11) was read by the Secretary *pro tempore* and was accepted.

WPA Records

The chairman, Dr. Guy L Richardson, Essex North, presented the report (Appendix No 12), which was accepted. Dr Lund moved that the physician referred to in the report be brought up before the Committee on Ethics and Discipline; this was seconded. After some discussion, chiefly concerned with the fact that the physician was only one of many, the motion was defeated. Dr. Conley brought up the question whether the WPA was supposed to maintain a list of physicians recommended by the local medical society. Dr. Richardson replied that Mr Burns, the State Compensation Officer, had asked for a list of physicians qualified to render service in severe accident cases but that the committee did not consider itself qualified to issue such a list and suggested that every physician licensed to practice in Massachusetts was so qualified.

Restoration to Fellowship

The Council voted to approve the reports of the committees recommending restoration of fellowship, with the usual provision regarding payment of dues, to twelve former members of the Society (Appendix No. 13); no action was recommended by the committee appointed to consider the application of one former member.

Nominating Committee

Dr. Allen G. Rice, Hampden, temporary secretary of the committee, presented the following list of nominations, which was read by the Secretary *pro tempore*:

- For president: Frank R. Ober, Suffolk.
- For vice-president: Edward P. Bagg, Hampden.
- For secretary: Michael A. Tighe, Middlesex North.
- For treasurer: Charles S. Butler, Suffolk.
- For orator: William B. Castle, Suffolk.

There being no further nominations, it was voted that the nominations be closed and that the Secretary *pro tempore* cast one ballot for the nominated officers. The Secretary *pro tempore* announced that he had cast the ballot, and the officers were declared to be duly elected.

APPOINTMENT OF COMMITTEES

The President then announced his nominations for appointment to the various standing committees for 1941-1942. These nominations, with the exception of those for the Committee on State and National Legislation, were duly approved by the Council (the list will be published with the proceedings of the Society in the July 3, 1941, issue of the *Journal*).

As members of the Committee on State and National Legislation, the President nominated the following: H. C. Marble, Suffolk, chairman; B. F. Conley, Middlesex South; C. A. Robinson, Suffolk; E. M. Chapman, Suffolk; L. M. Felton, Worcester. Dr. Norman A. Welch, Norfolk, nominated D. L. Lionberger, Norfolk. Drs. David L. Halbersleben, Charles J. Kickham and Francis P. McCarthy, Norfolk, and Dr. Conley spoke in favor of the retention of Dr. Lionberger on the committee. Tellers were appointed, and the ballots distributed. In reply to a question whether a ballot would be thrown out if less than five names were included, the President replied that it could not, but that he assumed that each councilor would vote for five members. The tellers retired to count the vote.

The Council approved the appointment of committees to consider petitions for restoration to fellowship of two former members of the Society (Appendix No. 14), it being understood that these

committees would not function if the proposed changes in the by-laws were accepted at the annual meeting of the Society.

The appointment of Dr. Fletcher H. Colby as representative from the Society to the Hospital Council of Boston and that of Dr. A. Warren Stearns to confer with the Committee on Medical Health for Defense were confirmed.

INCIDENTAL BUSINESS

It was voted that the Secretary be authorized to issue a new copy of the by-laws, provided the proposed changes were accepted at the annual meeting of the Society.

The action of the censors of the Plymouth District Medical Society in acting favorably on the applications of Dr. Bernard H. Beuthner, of Middleboro, and Drs. Walter Goldstein and Molyneux P. Mathews, of Brockton, was approved, these names having been received by the Secretary *pro tempore* too late to be included in the official list of applicants that was published in the *Journal*.

Dr. Monks moved that the thanks of the Council be extended to Dr. DeNormandie for his work as chairman of the Committee on Ethics and Discipline; this was seconded and unanimously voted.

The meeting adjourned at 12:45 p.m., to reconvene at the close of the annual meeting of the Society on May 22.

* * *

The reconvened meeting of the Council was called to order in the Sheraton Room of The Copley-Plaza at 12:35 p.m. on Thursday, May 22, by the President, following the annual meeting of the Society. No attendance was taken, but approximately 150 councilors were present.

Dr. Ralph R. Stratton, Middlesex East, a member of the Nominating Committee, presented the name of Dr. George L. Schadt, Hampden, as president-elect. It was voted that the nominations be closed and that the Secretary *pro tempore* cast one ballot for the nominated officer. This was done, and Dr. Schadt was declared to be duly elected.

Dr. Leroy E. Parkins, Suffolk, then reported the vote for the Committee on State and National Legislation as follows: Dr. Marble, 148; Dr. Conley, 173; Dr. Robinson, 149; Dr. Chapman, 140; Dr. Felton, 121; Dr. Lionberger, 159. The President declared Drs. Marble, Conley, Robinson, Chapman and Lionberger elected. As his parting words, he urged that the right and privilege of the Council to make nominations from the floor for positions on standing committees be exercised with great caution and discrimination, since

the nominations made by the president of the Society, whom the Council elects and in whom it is supposed to place its trust, carry with them an intimate knowledge of the work of the committees and of the welfare of the Society.

Dr. Tighe then presented a resolution (Appendix No. 15) requesting the appointment of a committee by the American Medical Association, to be known as the Committee on Legal Medicine; he moved its adoption, and it was so voted.

The matter of the tabled report of the Committee on State and National Legislation was brought up. The Secretary *pro tempore* said that he had not received a report from the committee; Dr. Marble was not present. Dr. Lund, former chairman of this standing committee, stated that since he had frequently made informal reports of the type presented by Dr. Marble and since these had always been accepted without question, he believed the report should be accepted. Dr. Morgan called attention to the fact that, if the constitution and by-laws of a chartered organization are not properly followed, its actions may be challenged in a court of law and warned that, if by-laws do not please and satisfy, they should be changed—never broken.

The meeting adjourned at 1:03 p.m.

ROBERT N. NYE, *Secretary pro tempore*

APPENDIX NO. 3

REPORT OF THE COMMITTEE ON ETHICS AND DISCIPLINE

During the year the Committee on Ethics and Discipline has held five regular meetings and one special meeting, over which the president of the Society presided. Reports have been made to the Council of all but the last regular meeting.

Since the last meeting of the Council, the committee has answered many requests for information and advice and has called the attention of several fellows to unethical publicity on their part.

One fellow made rather extravagant statements regarding his hospital in a radio broadcast during a health week sponsored by a local organization. The fellow's attention was called to the fact that his address did not conform to the general principles governing publicity as proposed by the Committee on Ethics and Discipline and accepted by the Council on February 2, 1938.

The committee appreciates the fact that there may be many radio talks by fellows of which it hears nothing. When criticism of a radio address is made, the committee is often asked why it does not criticize all fellows who speak on the radio. The answer, of course, is clear. The committee cannot sit by the radio day by day. Only when such addresses are called to its attention can it take up the matter with individual fellows. The committee does, however, urge all fellows to become familiar with the general principles governing publicity that the Council accepted three years ago. If these suggestions were conscientiously followed, the Committee on Ethics and Discipline would have little or no criticism to make regarding publicity.

During the year the committee has asked for the resignation of three fellows. One has already been acted on. Two resignations have been received since the last meeting of the Council, one because of participation in the procuring of an abortion and the second because of deceit in the case of an automobile accident. In the latter case the fellow asked for a hearing before the Committee on Membership and the Committee on Ethics and

APPENDIX NO. 2

REPORT OF THE COMMITTEE ON MEMBERSHIP

The committee recommends:

1. That the following named four fellows be allowed to retire under the provisions of Chapter I, Section 5, of the by-laws:

Bright, James C., Fall River
Knowlton, Charles D., Rockport
Libby, Mildred A., Worcester
Vickery, Lucia F., Jamaica Plain

Discipline. This hearing was given, following which it was the unanimous opinion of the combined committee that the fellow be asked to resign. The report on these two fellows has already been presented to you by the Committee on Membership.

ROBERT L. DeNORMANNE *Chairman*

APPENDIX NO 4

REPORT OF THE COMMITTEE ON MEDICAL EDUCATION AND MEDICAL DIPLOMAS

The Committee on Medical Education and Medical Diplomas during the past year has devoted its efforts chiefly to drawing up changes in the bylaws relative to the admission to the Society of the graduates of foreign medical schools and unrecognized domestic medical schools. The number of foreign graduates applying for admission to the Society during the last twelve months has been 92. Of these 64, or 69 per cent have been approved by this committee for examination by the censors and 59 have been admitted as fellows of the Society. During this same time the number of graduates of unrecognized domestic medical schools applying has been 80. Of these 27, or 33 per cent, have been approved by this committee for examination by the censors, and 23 have been admitted as fellows of the Society. Therefore, 21 per cent of all admissions to the Society were graduates of foreign schools, 8 per cent were graduates of unrecognized domestic schools while 71 per cent were graduates of approved schools.

There is every indication that soon the number of applicants from foreign schools will decrease while the number of applicants from unapproved domestic schools will show no such decrease. This committee in approving applicants intends to continue to follow the policy enunciated in its last report which was approved by the Council at its recent special meeting.

Two regular meetings were held before the November and the May examinations and one special meeting to consider the case of an applicant about whom the committee had received widely divergent reports.

JOHN P. MONKS *Chairman*

APPENDIX NO 5

REPORT OF THE COMMITTEE ON PUBLIC HEALTH AND THE SUBCOMMITTEE ON PUBLIC EDUCATION

The weekly broadcasts over WAAB the Green Lights to Health, were carried on from November to April a somewhat shorter period than in recent years. The committee has no means of knowing how large an audience it had or how much it accomplished in the matter of health education.

The president of the Society referred to the committee a letter he received from Dr. Edgar C. Yerbury, secretary of the Committee on Mental Health for Defense, a joint undertaking of the Massachusetts Department of Mental Health and the Massachusetts Society for Mental Hygiene. They requested that the Massachusetts Medical Society join with other organizations in sponsoring this movement and appoint a representative to work with them. The committee voted approval of this plan and requested the President to nominate a representative from the Society.

A letter from Dr. Donald B. Armstrong, third vice-president of the Metropolitan Life Insurance Company, was referred to the committee. The company is launching this month a nationwide educational campaign on diabetes and wants the members of this society to be informed of their plans. The field agents of the company will contact individual physicians and supply them with diet and identification cards and other printed matter. Suitable leaflets will also be distributed to the public. It is believed that this material will help both physicians and patients.

At the meeting of the Council on February 5, 1941, a letter from Dr. Herbert Margolis, of the Oral Hygiene Council of Massachusetts, was read and referred to the Committee on Public Health. In brief, this letter, which was printed in the proceedings of the Council (*New Eng J Med* 224 380, 1941) stated that whereas children are not marked absent, "tardy" or "excused" when they attend dental or hospital clinics during school hours, they are so marked when they have an appointment at a dentist's or physician's office. This would seem to penalize children whose parents finance such work.

The Oral Hygiene Council was planning to urge the Boston School Committee to amend its regulations "so that it would excuse a child for medical and dental service which of course covers private medical and dental service as well as clinic and hospital service." If this change were adopted by the Boston School Committee, it was hoped that other communities could be induced to follow its example. The support of the Massachusetts Medical Society in bringing this about was asked for.

Dr. Patrick J. Foley, of the Oral Hygiene Council, met with the Committee on Public Health. In the discussion it was apparent that some members of the committee felt very strongly that the schools were over-emphasizing the importance of a perfect school attendance, with the result that children were attending school when really ill, to the detriment of their own health as well as to others through the spread of communicable disease. The committee voted to recommend to the Council that the Massachusetts Medical Society join with the Oral Hygiene Council in requesting the Boston School Committee to make this change in its regulations, hence the following motion is recommended.

That the Massachusetts Medical Society join with the Oral Hygiene Council of Massachusetts in requesting the Boston School Committee to amend its rules and regulations so that a child may be excused for medical and dental service without being considered an absentee.

FRAZIS P. DE WY, *Chairman*

APPENDIX NO 6

REPORT OF COMMITTEE ON MEDICAL DEFENSE

It is with regret that we report the recent death of our committee member Dr. F. P. Sweet, of Springfield. He was one of the members of the original Committee on Medical Defense and faithfully served continuously until his death.

During the past year only one additional member of the Massachusetts Medical Society has required legal aid in a malpractice suit. In this case, the defendant is insured and is seeking the added support of our attorneys.

One case was satisfactorily disposed of during the year. Another case was tried before a jury in December, 1940, and a verdict was rendered in favor of the defendant. The plaintiff, however, taking the case to the Supreme Court.

Court, so that it cannot, as yet, be considered closed. An additional case appears to be inactive and will probably not be pursued farther. A total of eight cases are pending at this time.

During the year, an attempt was made to circumvent the two-year statute of limitations, which is based on the date of the alleged malpractice. In this case, the suit was brought by the executor of an estate within two years of his appointment but after the time limit of the alleged malpractice. It is of some importance that this exception was not allowed by the courts.

The committee is well pleased with the management of malpractice suits by our legal advisers.

A. W. ALLEN, *Chairman*
E. D. GARDNER
W. R. MORRISON
HORATIO ROGERS, *Secretary*

APPENDIX NO. 7

REPORT OF THE COMMITTEE OF ARRANGEMENTS

We offer the program of this meeting as our report to date. The work of the committee is still unfinished, and we shall render a final report after the annual meeting is over.

EDWARD J. O'BRIEN, JR., *Chairman*

APPENDIX NO. 8

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The Council has already endorsed the proposal of the Blue Cross to extend its privileges to physically qualified individuals who have no opportunity to associate themselves with groups. The Committee on Public Relations has considered the form and fee for physical examination of these candidates and recommends your approval of a \$3 base fee, supplemented by extra charges if special examinations are required.

The committee met with Dr. B. W. Mandelstam, medical adviser to the Department of Public Welfare of the Commonwealth of Massachusetts, and considered certain mutual problems.

In a very few communities in this state the hospitalized welfare recipient is charged a fee for physicians' services (for example \$50 for a major operation and \$15 for the assistant). The State cannot allow reimbursement to the town if the town pays these fees, so some cities or towns are sending these cases to hospitals in other communities where no charges for welfare care are permitted by the hospital. The Committee on Public Relations voted not to interfere now with this situation but instead asked the Special Committee for the Study of Welfare Medical Care—Drs. Bagnall, Hunt, Hornor, Duncombe and Pelletier—to endeavor to arrange a fee table for professional service to hospitalized welfare cases throughout the State and to consider the advisability of having the local committees on public relations referee all bills for medical care.

The special committee believes that the profession must come to the position of assuming a degree of responsible censorship wherever there exists an unenlightened tendency to violate principles of fair practice. Some state welfare administrators have regulated these things without first giving the local professional organization an op-

portunity. In this state, the Franklin District Medical Society now supervises all bills for welfare medical care. We recommend that this practice be extended to all district committees on public relations or to special committees, and that these committees be authorized by their district societies to review bills for welfare medical services and to recommend adjustments wherever indicated.

The special committee believes that this is not a strategic time to make endeavors toward procurement of a fee schedule of payments by the State to physicians on welfare cases in hospitals. The whole philosophy of charitable medical service in hospitals by staff physicians is involved. We agree that it may fairly be contended that staff physicians should be compensated for both inpatient and outpatient service, but unless the practice of over a century is to be changed, with all that it involves, evolution rather than revolution is the method of choice.

The Committee on Public Relations recommends that the Council approve the requirement that the delegate to the Committee on Public Relations of the Massachusetts Medical Society be chairman of his district committee and that he be a member of the Council.

E. S. BAGNALL, *Secretary*

APPENDIX NO. 9

REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

The postgraduate extension courses for the academic year 1940-1941 ended on April 30. In the past few years, the Society has co-operated with the Massachusetts Department of Public Health, the United States Public Health Service and the Federal Children's Bureau in providing this type of postgraduate teaching for all the physicians of the Commonwealth. The Society has appropriated \$1000 to aid in organizing the work; the government agencies have paid all other expenses.

Courses were given in twenty places with enrollment as follows:

DISTRICT	PLACE	1939	1940	1941
Barnstable	Hyannis	33	23	22
Berkshire	Pittsfield	45	50	50
Bristol North	Taunton	31	20	18
Bristol South	{ Fall River	36	22	42
	{ New Bedford	34	54	42
Essex North	Lawrence	48	52	40
Essex South	Salem	54	59	54
Franklin	Greenfield	27	47	34
Hampden	{ Holyoke	30	40	16
	{ Springfield	40	100	36
Hampshire	Northampton	30	32	33
Middlesex East	Melrose	21	54	40
Middlesex North	Lowell	21	25	32
Middlesex South	Cambridge	50	60	25
Norfolk	Norwood	(no course)	26	32
Norfolk South	Quincy	25	20	25
Plymouth	Brockton	35	27	23
Suffolk	Boston	180	172	95
	{ Milford	20	30	30
Worcester	{ Worcester	(no course)	45	(no course)
Worcester North	Fitchburg	35	26	25
Totals		795	964	718

As a part of the national antivenereal disease campaign, the committee has co-operated with the government agencies in providing clinical teaching in gonorrhea and syphilis in the outpatient departments of the Boston Dispen-

sary and Massachusetts General Hospital. The teaching clinics were open to any registered physician in Massachusetts. It is hoped that these clinics will continue to be of service to those clinicians who desire to know more about the diagnosis and treatment of venereal disease.

In the autumn of 1940 a postgraduate library extension service was inaugurated, this project has been under the direct supervision of the Boston Medical Library. The references have been planned to supplement the postgraduate extension courses, so far there has not been time enough to finish all this service. Twenty bibliographies were completed, fifteen physicians requested loans of one or more sets of references. Dr. Henry R. Viets, the director believes that this service is worth while and that it should be enlarged and completed so that physicians may have clinical references readily available. This project has been started as a public health service and has been made possible by a grant of funds from the United States Public Health Service, on recommendation of the Massachusetts Department of Public Health.

Plans have been made for the New England Postgraduate Assembly to be given next fall on Wednesday and Thursday, October 29 and 30. The program is almost completed and will be published early in September. The list of speakers is as follows:

- Dr. Frank E. Adair, New York City (gynecology)
- Dr. J. Burns Amberson, New York City (tuberculosis)
- Dr. J. J. Bloomfield, Washington, D. C. (industrial medicine)
- Dr. William Darrach, New York City (fractures)
- Dr. John S. Lockwood, Philadelphia (chemotherapy)
- Dr. H. M. Marvin, New Haven (heart disease)
- Dr. William S. McCann, Rochester, New York (renal diseases)
- Dr. Damon B. Pfeiffer, Philadelphia (surgery)
- Dr. Homer F. Swift, New York City (rheumatic fever)
- Dr. George W. Thorn, Baltimore (endocrine disorders)
- Dr. Norris W. Vaux, Philadelphia (obstetrics)

These plans as well as the extension program are subject to change depending on the state of the national emergency.

FRANK R. OBER, *Chairman*
LEROI E. PARKINS, *Secretary*

APPENDIX NO 10

REPORT OF THE COMMITTEE ON INDUSTRIAL HEALTH

We are still working toward the end that all industry in the Commonwealth of Massachusetts, large and small, and all physicians directly or indirectly interested in those industries will receive special information regarding the health problems of industry.

Various methods have been used to present our case, particularly to the physicians. The *Journal* has been invaluable in presenting our cause, through the written reports of committee activities and also through published industrial medical case histories, and questions and answers about industrial medical problems.

The committee held monthly meetings throughout the fall and winter. The last meeting was on April 10 and is of particular interest because of the interesting group of invited guests. There were present an industrial executive as a representative of Associated Industries, a member of the Industrial Accident Board, a member of the Department of Labor, Division of Industrial Hygiene, two mem-

bers of the Harvard School of Public Health, a member of the United States Navy and two officers of insurance companies that handle workmen's compensation insurance. These guests were invited to acquaint them with the work being done by the Massachusetts Medical Society through this committee and also to get from them the ideas of the agencies that they represent and that should be vitally interested in our program.

The committee is at present tabulating statistics on all physicians in Massachusetts who are engaged in industrial medical practice to any extent. This work is being done for the Committee on Medical Preparedness of the American Medical Association.

W. IRVING CLARK, M.D., *Chairman*
LOUIS R. DANIELS, M.D., *Secretary*

APPENDIX NO 11

REPORT OF THE COMMITTEE ON THE ARMY MEDICAL LIBRARY AND MUSEUM

The chairman of this committee has been active in the last three months and on one occasion visited Washington and the Army Medical Library. With Surgeon General Magee, United States Army, and Colonel Jones, librarian of the Army Medical Library, various sites were inspected in Washington for the new building. A site was finally chosen on Capitol Hill and information has been received that the library will be erected there. A bill is now before Congress to purchase the land, the site having been authorized by the Planning Board of Washington. Your committee feels reasonably certain that the library will be erected on the proposed site and that building will be started within a year.

As there are likely to be matters coming up in the course of the next few years in regard to this project, it is hoped that the committee will be continued.

HENRY R. VIETS, *Chairman*
ROBERT B. OSGOOD
BENJAMIN SPECTOR

APPENDIX NO 12

REPORT OF THE COMMITTEE TO EQUALIZE DISTRIBUTION AMONG PHYSICIANS OF MEDICAL SERVICE TO WPA EMPLOYEES

In accordance with the plan reported to the Council on February 5, a member of our committee visited the WPA office in Boston each month. A listing of the total amount of fees each physician has received for this work has been completed. This listing covers the entire time the WPA has been in operation—about three and a half years. Some physicians have received more than \$3000 from the federal government during this period.

In order to start the equalization process, it is planned to remove from the list of available physicians all those who have received \$500 or more for this kind of service. There would be an important exception to this ruling, agreed on by the State Compensation Officer and your committee, namely, when an injured WPA employee has a family physician, he may still be allowed to go to him for treatment. The process of equalization of fees would necessarily be slowed by this means, but the principle of free choice seems of more importance. In this connection, it is essential that every means be taken

to prevent timekeepers and foremen from influencing the injured workman in his selection. Too much of that sort of thing has occurred in the past.

Certain physicians, by reason of the type of practice they have, tend to get more WPA patients than others. This appears inevitable, and so long as the physician selected is the family physician, our committee believes that it is just. Exact equalization of fees cannot be brought about.

One doctor has been overenergetic and particularly persistent in his attempt to get more WPA work. He has written repeatedly to the State Compensation Officer, describing his successful practice, his qualifications and his equipment. He complained that he was not receiving his share of the WPA cases at that time. He further stated that his income-tax returns would prove that he had the best practice in town. A check of the records in the WPA office revealed the fact that this complaining physician had handled more than one third of all the WPA injury cases in that town, and that he had received in fees nearly 50 per cent of all the money paid to the seven physicians in that town. He went so far as to request a hearing before the State Compensation Officer, and an appointment was given to suit his convenience. One of our committee inconvenienced himself to be present, but the complainant failed to appear, nor did he bother to explain his failure to appear. Needless to say, he was notified that no further WPA cases would be referred to him until a more equitable distribution had been arrived at.

In another district, sixteen physicians were removed from the listing because the money they had received greatly exceeded that received by all other physicians.

For your information, during the three and a half years of WPA operation in Massachusetts, \$1,047,401 has been spent for the care of approximately fifteen thousand injured workmen. The portion paid to physicians has not been totaled. Hospital charges are a big item.

Discussion of this report and suggestions by the Council would be welcomed by your committee.

GUY L. RICHARDSON, *Chairman*

APPENDIX NO. 13

REPORTS OF COMMITTEES APPOINTED TO CONSIDER RESTORATION TO FELLOWSHIP

Restoration to fellowship, with the usual provision regarding the payment of dues, was recommended for the following former members:

Bernard H. Appel, Brighton (Committee: Max Ritvo, David Stern and R. H. Aldrich).

Harold I. Cohen, Lynn (Committee: C. F. Twomey, Bernard Appel and C. L. Hoitt).

Frederick E. Cruff, Norwell (Committee: B. H. Peirce, R. F. Littlehale and Charles Hammond).

J. Frank Curtin, North Abington (Committee: J. H. Dunn, J. M. Peckham and Jonah Fieldman).

Leroy S. Ford, Keene, New Hampshire (Committee: S. N. Vose, H. L. Albright and W. H. Lacey).

Maurice Gerstein, Brookline (Committee: C. J. Kickham, E. L. Kickham and Albert Ehrenfried).

William R. Hill, Brookline (Committee: C. J. Kickham, J. A. Hennessey and R. J. Donovan).

Elihu I. Lewis, Boston (Committee: W. T. O'Halloran, M. D. Altschule and N. L. Fineberg).

Coval H. Liverpool, West Somerville (Committee: C. W. Finnerty, J. E. Gillis and Herbert Chelerton).

John L. O'Toole, Haverhill (Committee: W. W. Ferrin, L. R. Chaput and G. J. Connor).

Nathan Silverman, Lawrence (Committee: J. J. Deacy, J. J. Kelleher, Jr. and J. A. Levek).

Thomas V. Uniac, Lawrence (Committee: R. V. Baketel, V. A. Reed and H. F. Dearborn).

No action was recommended in regard to the petition of Anthony P. Carogana, Chelsea (Committee: W. J. Brickley, J. A. Smith and W. E. Garrey).

APPENDIX NO. 14

COMMITTEES APPOINTED TO CONSIDER PETITIONS FOR RESTORATION TO FELLOWSHIP

The following committees were appointed to consider the petitions for restoration to fellowship of the following two former members.

For Edward C. Messer, Dorchester:

W. J. Walton, D. J. McSweeney and J. J. Meehan.

For Nathan Pulsifer, Lowell:

A. R. Gardner, D. J. Ellison and H. W. Jewett.

APPENDIX NO. 15

RESOLUTION PRESENTED BY DR. MICHAEL A. TIGHE

WHEREAS, Throughout the greater part of the United States the application of medical knowledge and skill to the needs of justice is seriously impaired because medicolegal investigations of the cause and circumstances of deaths are conducted under the quasijudicial political office of county coroner; and

WHEREAS, the Commonwealth of Massachusetts, due largely to the efforts of the Massachusetts Medical Society, was the first state in the United States and for that matter the first community in the English-speaking part of the world to abolish the coroner's office and replace it by that of medical examiner; therefore, be it

RESOLVED, that the delegates of the Massachusetts Medical Society to the forthcoming meeting of the American Medical Association in Cleveland be instructed to recommend to the House of Delegates that it appoint a committee of three, to be known as the Committee on Legal Medicine, and that the aforesaid committee be instructed:

To survey the manner in which legal medicine, so far as it is concerned with the activities of the coroner's office, is being practiced in various parts of the United States;

To consult with the Medicolegal Committee of the American Bar Association to determine how best to improve the practice of legal medicine; and

To acquire and make available to the medicolegal committees of the various state medical societies such information as may be useful to them in their efforts to abolish or improve the coroner system in their respective states.

MEDICAL PROGRESS

DIAGNOSTIC ROENTGENOLOGY

The Flat Film of the Abdomen; Myelography: Air versus Iodized Oil;
Fibrocystic Disease of Bone

RICHARD SCHATZKI, M.D.*

BOSTON

THE FLAT FILM OF THE ABDOMEN

THE flat film has for many years played an important role in the examination of the abdominal organs. Owing to many technical improvements, the quality of such films has greatly improved in recent years, and this has simultaneously broadened the scope of the roentgenologist.

No other single x-ray film gives so much information as the flat film, which reveals not only the disseminated or generalized bone diseases, such as metastatic tumors, diffuse osteoporosis and Paget's disease, but also a vast variety of soft-tissue abnormalities. It is impossible to include them all in this review, for a casual count shows that more than a hundred conditions are at times diagnosable by these films. Hence, this report is limited to the non-skeletal parts of the abdomen, and emphasizes those conditions to the diagnostic significance of which clinicians have hitherto paid insufficient attention, as well as those subjects to which recent contributions have been made. No attempt will be made to quote the literature in detail.

A few words about the preparation of the patient are in order, since an adequate examination of the abdomen is rendered impossible by an incompletely emptied colon or a partially filled bladder. The patient should have, unless it is contraindicated, a good cathartic, preferably castor oil, as well as a cleansing enema. Pitressin may be useful in emptying the bowel. The patient should void before the films are taken.

In a review of this subject it may be worth while to remember the elementary fact that x-rays differentiate objects adjacent to each other only if the objects are of different translucency to the rays. Generally speaking, there are only four different densities to x-rays in the body. Arranged in groups, from the densest to the lightest, they are: calcified areas, including bone; all soft tissues, excluding fat, and all body fluids, excluding chyle; fat and chyle; and air and other gases. An organ becomes visible only if the adjacent tissue belongs to a group above or below its own x-ray density.

The Spleen

In most flat films of the abdomen, the lower edge of the spleen, as well as parts of its lower medial border, is visible. Occasionally, the upper part of the medial border is seen within or medial to the air-filled stomach. Statistics on the exact size of the normal x-ray shadow of the spleen do not exist, to my knowledge, but in the daily clinical routine the roentgenographic determination of the size of this organ has proved reliable.

Enlargement of the spleen is usually readily seen on a flat film. This fact can be utilized clinically, particularly in cases in which the determination of the size of the spleen by percussion and palpation is rendered difficult or doubtful. The characteristic shape of the x-ray shadow of the spleen has proved useful in cases in which it was clinically doubtful whether a mass in the left upper quadrant represented the spleen. A lateral flat film may be of particular help in such a case.

The Liver

The superior surface of the liver is clearly shown by the position of the diaphragm. Its lower edge can be seen in contrast with the adjacent colon or small intestine on most flat films, thus outlining the size of this organ. Pfahler¹ described special studies on the x-ray measurements of the liver. Although an exact interpretation of liver size is made difficult by its distortion or by any unusual tilt of the organ, gross changes in its size are readily recognizable if the lower edge is visible. Marked anomalies in the shape of the liver, as produced by syphilitic lobulation or by large primary tumors, may be seen on the flat film. Superficial lobulation, produced by metastasis, is not visible.

Liver abscesses may produce no change from the normal appearance in the flat film. On the other hand, multiple abscesses may cause a generalized enlargement of the organ, and some liver abscesses may produce a localized lobulation of the diaphragm. In such cases, fluid may be found in the costophrenic angle. Gas formation in an abscess can be easily demonstrated, especially if a fluid level is shown by using some view with horizontal direction of the x-rays. Calcification occasionally occurs in old abscesses.²

All articles in this series will be published in book form the current volume is *Medical Progress: An annual, 1940* (Springfield Illinois: Charles C. Thomas Company 1941 \$4.00)

*Instructor in roentgenology Harvard Medical School roentgenologist, Massachusetts General Hospital

The diagnosis of infection within the bile ducts is at times difficult clinically. It is, therefore, of interest that Berg³ recently described 4 cases in which, owing to the action of gas-forming bacilli, a more or less extensive demonstration of the bile-duct system occurred on the flat film. More commonly, air filling of the bile ducts is produced by an abnormal postoperative or spontaneous communication of the bile ducts with the gastrointestinal tract. If the communication is spontaneous, it is in rare cases due to an eroding peptic ulcer or neoplasm, but usually it is produced by the penetration of a gallstone. Air in the bile ducts, if found in a patient with ileus, is highly suggestive of gallstone ileus, even though the obstructing stone itself cannot be demonstrated within the distended air-filled and fluid-filled loops of intestine.⁴

The Pelvic Organs

The use of the flat film in the study of pelvic disease is important, but not generally appreciated. Whereas at times the flat film may merely reveal the presence of some abnormality of the pelvic organs, at other times a definite diagnosis can be made. To state whether a pathologic soft-tissue mass is malignant or benign, or inflammatory, or indeed, to name its true origin, may at times be extremely difficult. Nevertheless, the value of the film is manifest by the esteem that experts in manual examination have for it. Needless to say, a particularly well-cleansed rectum and sigmoid and an empty bladder are necessary for a successful visualization of these organs. Films with varying tilts of the x-ray tube may prove helpful.

On a good film the normal uterus is usually visible as an ovoid shadow caused by the projection of the anteflexed organ. Fibroids produce uterine enlargement, usually eccentric; in later years they are commonly calcified. Large intramural fibroids may produce a symmetrical enlargement of the uterus, simulating pregnancy and differing only in the absence of fetal bones. Similarly, it may be difficult or at times impossible to differentiate large ovarian cysts from such fibroids. To diagnose carcinoma of the uterus is not possible, but the flat film may give helpful information of the extent of parametrial involvement in advanced cases.

Inflammation within the parametrial tissues often produces a localized disappearance of the uterine outline. In acute or subacute processes, the pelvic subperitoneal fat layer, which is normally clearly visible on flat films, becomes edematous in the inflammatory area, and hence invisible. Abscesses can be seen as a more or less diffuse density filling the pelvic cavity, and at times may have an appearance that is difficult to distinguish from that of tumor.

Normal ovaries are occasionally seen on flat films. Ovarian cysts produce localized, round, soft-tissue shadows, the size of which shows great variation. Even small cysts may be seen on flat films, and not infrequently such cysts have proved to be palpable only at a second manual examination, after their presence had been suggested by the x-ray film.

Other ovarian tumors may produce shadows of varying size and shape, and some of them are definitely diagnosable by the flat film. Dermoids not infrequently contain incompletely developed teeth or bones. A correct differentiation from teratomas may be impossible; however, a diagnosis of dermoid may be possible even in the absence of calcified masses.⁵⁻⁷ This is because dermoids contain sebaceous material, which is more translucent than the capsule, thus producing the x-ray appearance of a "radiolucent tumor."

Cystadenoma and cystadenocarcinoma of the ovary are often identifiable by the presence of small calcified psammoma bodies, large enough to be visible on flat films. These areas of calcification may betray the presence of ovarian tumors at a preclinical stage⁸; in tumors of long standing the calcifications may become very diffuse, filling large portions of the abdominal cavity. On the other hand, even large cystadenomas may exist without visible areas of calcification.

Inflammatory and neoplastic soft-tissue masses arising in the bony pelvis are usually easy to recognize.

This description of the possibilities of the flat-film examination of the pelvis should not produce an exaggerated impression of its practical value. The presence of many of the processes mentioned certainly cannot be excluded if they are not visible on the film, nor is a roentgenologic differential diagnosis possible in many cases in which disease is visible.

The Retroperitoneal Organs

The normal retroperitoneal space offers a fairly characteristic appearance on the flat film, an appearance created by the fat that surrounds the kidneys and the retroperitoneal muscles (psoas and lumbosacral muscles). As previously noted, fat is of a different density to x-rays than other soft tissues, and for this reason these organs are made visible on the flat film by the fatty tissue surrounding them. Thus, the retroperitoneal organs of an obese person are better visualized than those of a thin person. Any localized disappearance of the retroperitoneal outlines suggests disease in this area, whereas a generalized loss of outline occurs in the presence of extensive disease within the abdomen, such as massive ascites or a large ovarian

tumor. Here again, the adequate preparation of the patient is of paramount importance, since air or fecal material may seriously obscure the retroperitoneal structures.

A localized space consuming process in the retroperitoneal tissue, whether tumor, abscess or hematoma, produces a homogeneous soft tissue shadow obscuring the normal retroperitoneal outlines. The differential diagnosis between the three conditions may at times be impossible, but usually the position of the mass and the sharpness and shape of its edge, as well as the presence and structure of calcification within or around it, permit a fairly accurate diagnosis.

Gas in the retroperitoneal spaces may be due to gas producing bacilli, or more rarely to retroperitoneal perforation of the duodenum or colon. The development of fat necrosis presents a peculiar mottled appearance.

The Pancreas

Although the normal pancreas is not visible on the flat film, Engel and Lysholm⁹ have estimated its approximate size by measuring on a lateral film the distance between the air-distended stomach and the spine. This distance they found increased in cases of pancreatic enlargement. Case,¹⁰ who recently reviewed the roentgenology of pancreatic disease, recommends the method.

Pancreatic cysts, with their characteristic round shape, are usually readily visible on a flat film. Occasionally large pancreatic carcinomas can be seen on flat films, but the roentgenologist must be content to diagnose a retroperitoneal tumor, perhaps venturing a guess at its pancreatic origin based on its location and its effect on the position of the kidneys.

On the whole, the flat film examination of the pancreas is still unsatisfactory.

The Kidneys

The kidneys are seen on most good flat films because of the fatty tissue surrounding them. Although normal kidneys vary greatly in size, pathologic variations in size are usually recognizable, such as small shrunken or large polycystic kidneys. Tumors and solitary cysts produce a localized enlargement of the kidney, and are usually impossible to differentiate on the flat film. If a tumor or cyst protrudes only slightly from the kidney surface, it may simulate a congenital lobulation of the kidney, an anomaly of no significance.

Renal stones are the commonest cause of calcification within the kidney outline, a detailed discussion of stones is beyond the confines of this report. Linear areas of calcification in a charac-

teristic arrangement within the pyramids of the kidneys represent calcium casts of the tubules, and are highly suggestive of the greatly increased calcium excretion found in hyperparathyroidism.¹¹ Calcifications in tuberculous abscesses of the kidneys are usually very characteristic, whereas the occasional calcifications in tumors are of less diagnostic significance.

The importance of the flat film in the diagnosis of perinephritic abscess has been emphasized for years. The most characteristic change is that of a localized disappearance of retroperitoneal structures (kidney shadow and psoas shadow). Scoliosis, elevation of the diaphragm and displacement of the kidney shadows are other signs found in this condition. Hemorrhage around the kidney may simulate the picture of perinephritic abscess; the changes, however, are usually more extensive. In cases of subcapsular hemorrhage, the involved kidney may remain clearly visible, with its shadow greatly enlarged.

The Adrenal Glands

Normal adrenal glands are not seen on the flat film. Tumors become visible only after they have reached large dimensions. In Addison's disease, the adrenal glands may be calcified, and I know of cases of previously unsuspected Addison's disease that were diagnosed first by the characteristic x-ray appearance of the calcified glands. On the other hand, such calcification does not necessarily establish the diagnosis of Addison's disease, because it is sometimes seen in the absence of adrenal insufficiency.

The Peritoneal Cavity

The value of the flat film for demonstrating air in the peritoneal cavity is well known. This examination is widely used whenever there is a question of a perforated viscus. The absence of demonstrable air does not, however, exclude the presence of such a perforation.

Large amounts of fluid in the abdomen are usually easier to ascertain clinically than by the use of the flat film. This film may, however, be of great assistance in differentiating large ovarian cysts and ascites. The characteristic displacement of air-filled bowel by the ovarian cyst usually permits a prompt diagnosis.

Diffuse peritonitis usually produces early paralytic ileus. In this condition, fluid may be seen to separate the dilated air-filled intestinal loops.

Localized intraperitoneal abscesses become visible if they contain gas. If they are large enough, they produce a homogeneous soft tissue shadow, which may be visible as such, for example, in the region of the appendix or in the pelvis. Laurell¹²

has shown how essential it is to watch for a disappearance of the normally visible subperitoneal fat layer in all those cases in which the abscess is close to the abdominal wall.

The Stomach

The air-filled and fluid-filled stomach is often seen on the flat abdominal film, a fact that must be known only to avoid misinterpretation. Cancer of the fundus may be visible on the flat film if the tumor deforms the gas bubble of the stomach, particularly on a film taken in the upright position. Recently a rare case of extensive calcification in a scirrhous carcinoma involving the greater part of the stomach has been reported.¹³ Usually, however, the flat film is of little or no help in the diagnosis of cancer of the stomach.

The Intestines

One of the most important functions of the flat abdominal film is the assistance it offers in the diagnosis of mechanical and paralytic ileus. The characteristic dilatation of air-filled and fluid-filled loops of small and large intestine becomes visible within six hours after the onset of the pathologic process.¹⁴ The roentgenographic appearance of ileus has been described in many excellent papers,^{15, 16} and it will not be further discussed here. The value of the flat film in these cases cannot be overestimated, but it should be emphasized that in most cases the differential diagnosis between mechanical and paralytic ileus is not possible.

The advantage of flat-film examination in cases of intussusception and volvulus has been stressed in recent papers.^{17, 18} A definite diagnosis of these conditions can often be made by this method.

Tumors of the small intestine commonly assume large dimensions and become visible on flat films. They often contain large irregular gas-filled cavities with a characteristic appearance.¹⁹

Miscellaneous

This report has not mentioned a large number of conditions in which the flat film may be helpful. Among them are gallstones, hydrops of the gall bladder, pancreatic stones, calcified mesenteric lymph nodes, kidney, ureteral and bladder stones, parasites (echinococcal cysts and cysticercosis), pregnancy, pneumatosis cystoides intestinalis, tuberculosis of the seminal vesicles, tuberculous or osteomyelitic paravertebral abscesses, mesenteric cysts, abdominal neuroblastomas and calcification and aneurysm of the abdominal aorta or its branches.

These conditions are referred to by name only because a complete discussion is impossible, not because the flat film is considered to be of less importance in these conditions. As a matter of fact,

in some of these abnormalities the study of the flat film has become a specialty within the specialty of roentgenology, for example, in the study of the appearances of early and late pregnancy.

To summarize the value of the flat film in one sentence, one may say that it allows a definite diagnosis to be made in a fair number of conditions, but that in an even greater number it focuses the attention of the examiner on a certain region of the abdomen and indicates in which direction further examination should go.

MYELOGRAPHY: AIR VERSUS IODIZED OIL

Progress in the x-ray examination of lesions of the spinal canal in the last two decades is intimately connected with the introduction of iodized oil (lipiodol) as a contrast substance. Small tumors that are not seen in simple roentgenograms become visible as defects in the column of oil; progress in the recognition of even smaller lesions, such as ruptured intervertebral disks, has recently been reviewed.²⁰

The introduction of iodized oil into the lumbar canal has, however, met with opposition ever since it was first recommended. The literature of the last fifteen years is filled with controversial evidence proving or disproving the harmfulness of the injected oil. This controversy has lately been reviewed.²¹

In recent years, the use of air or oxygen has been recommended as a substitute for iodized oil in the examination of the spinal canal. Chamberlain and Young²² have shown the method to be effective in demonstrating encroaching lesions, and their report has stimulated similar studies in other clinics. The special value of the method lies in the fact that the gases are rapidly absorbed, leaving no residue in the canal. The results of such studies have shown uniformly that a positive finding in an air myelogram is of diagnostic importance,²³ although not quite so reliable as a defect demonstrated by lipiodol.²⁴ A normal air myelogram was, however, found to be of very little significance, inasmuch as succeeding lipiodol injections often revealed pathologic processes. It therefore became necessary in cases in which the air myelogram had been negative to do a second examination with oil, and in these cases it was found that the second test was rendered less effective by the previous air injection.

The main drawback of iodized oil has been the fact that it remains indefinitely in the subarachnoid space after injection. This has always been the target of attack of those who condemn the use of oil, and it has produced some uneasiness in those who have continued using it. It has always been striking to me to see how freely the oil moves in

the subarachnoid space even many years after its injection, a finding that argues against any markedly irritating quality of the substance. Garland and Morrissey²⁵ recently re-examined 25 patients several months or years after the injection of 2 to 5 cc. of lipiodol, finding not only that the oil was still present in all cases, but that in two thirds it was discovered in the cerebral cavity. In spite of this, neurologic examinations showed that in none of the cases were there symptoms or signs that had not been present prior to the injection or could be attributed to the presence of the oil. It is interesting to note that undesirable effects have been particularly unusual in those clinics in which lipiodol has been used extensively. Hence, although gases are readily absorbed after air myelograms, the diagnostic value of the examination has been markedly limited. On the other hand, the use of lipiodol has given good results, but the oil has remained in the spinal canal indefinitely, unless removed at a subsequent operation. In search of an ideal contrast substance, Thorotrast has been tried, but reports about its practical usefulness are still wanting.

An unexpectedly simple solution of the problem has been described in a recent paper by Kubik and Hampton.²⁶ These authors have outlined a method that makes it possible to remove lipiodol from the spinal canal through an 18-gauge needle, after the examination has been completed. The patient is placed horizontally, face down, on a fluoroscopic table. A lumbar-puncture needle is introduced into the third lumbar space, with the patient still in the prone position. The oil is injected and the needle left in place during the fluoroscopic examination, which follows immediately. At the end of the roentgenologic examination, the oil is brought into the region of the needle tip by tilting the table and is withdrawn by gentle suction with a small syringe. By tilting the table, under fluoroscopic control, any remaining oil is brought to the point of the needle and removed. Since small droplets of oil may not be visualized with the fluoroscope, a film is taken before the needle is withdrawn, to make sure that removal of the oil has been as complete as possible.

This simple procedure has proved successful in the hands of the authors in over 50 cases. Some experience and strict adherence to a few rules mentioned by them make for successful removal of injected lipiodol. In principle, this method has disposed of the main objection to the use of iodized oil. It is obvious that lipiodol examinations of the spinal canal should not be performed unless definitely indicated, but there is reason to believe that an oil examination, if performed as described

above, is no more dangerous than a lumbar puncture.

FIBROCYSTIC DISEASE OF BONE

The diagnosis and classification of fibrocystic lesions of the bones has been, and still is to some extent, a rather difficult enterprise.

A bone cyst should be a well-defined bag containing fluid, if one uses the word "cyst" as in other parts of the body. Only a few bone lesions that clinically and roentgenographically are called "cysts" fulfill this strict definition. Many of these contain blood clots or living tissue, with or without the fluid mentioned above.

Roentgenographically it is impossible to see any difference between the density or structure of a fluid-filled bone cyst and that of a cyst containing fibrous or other soft-tissue masses. It seems necessary to recognize this difficulty, although it appears of questionable value to confine the use of the word "cyst" to the strict definition given above.

The classification of these bone lesions, at first purely on a descriptive basis, led to a great deal of confusion, because of the numerous syndromes named and because the etiology of such lesions remained unknown. With the advent of accurate etiologic information in only a few of these conditions, the number of bone-cyst syndromes has been markedly diminished, and the confusion considerably cleared.

The most revealing discovery was the establishment of an etiologic relation between several types of bone cysts and hyperfunctioning states of the parathyroid glands. Ever since von Recklinghausen described cases of osteitis fibrosa cystica generalisata, with multiple cystlike areas scattered throughout the skeleton, this peculiar condition has puzzled roentgenologists, anatomists and clinicians. These areas may be in the medullary part of the bone, but more commonly are in the cortex. Histologically they represent either giant-cell tumors or cysts. They may be single, but are often multiple. In addition to these lesions there usually is severe generalized decalcification of the whole skeleton. This combination of cystlike areas and decalcification produces a characteristic x-ray appearance.^{27, 28} Blood chemical studies show the well-known disturbance of calcium metabolism, with a high serum calcium, a low serum phosphorus and a high serum phosphatase.

The relation of this disease to hyperfunction of the parathyroid glands was postulated many years ago, but not until Mandl cured a patient with osteitis fibrosa cystica generalisata by removal of a parathyroid tumor was this proved. The clinical entity has since been worked out in many excellent papers.²⁹

The successful explanation of osteitis fibrosa cystica generalisata prompted further attempts at explaining other cystic bone lesions as being due to a hyperfunction of the parathyroid glands or other endocrine organs. All these attempts have failed. Although a definite etiology has not been found for other bone cysts, another syndrome connected with fibrocystic bone disease has been established in recent years.

In 1937, Albright and his associates³⁰ described a syndrome in which cystlike areas in various bones play an important role. The syndrome consisted of multiple bone lesions with a marked tendency to be unilateral and with the histologic picture of osteitis fibrosa, round, nonelevated pigmented areas on the skin, which tended to be on the same side as the bone lesions, and endocrine dysfunction, which in females was associated with precocious puberty.

Albright and his associates deserve credit for emphasizing the combination of the abnormalities mentioned above as representing a characteristic and not too uncommon entity, although lesions similar to those considered by them had been described, mainly in case reports, in previous years under various names (localized osteitis fibrosa, focal osteitis fibrosa, osteodystrophia fibrosa unilateralis and so forth).

The bone lesions are of interest and importance. In most cases several bones are involved, the distribution of the disease being spotty and the uninvolved bones appearing normal. The lesions have a tendency to be regional and are consequently often unilateral, although not necessarily so. The bones in the involved areas are either slightly or markedly increased in size, with cystlike areas of rarefaction varying in size and shape and involving both cortex and medulla, in long as well as in flat bones. The epiphyses often escape involvement. Precocious bone age and early union of the epiphyses are part of the syndrome. The skull is commonly involved, particularly the frontal and occipital bones. Usually the cystlike areas fade out gradually, whereas others are well defined. The involved bone may be increased but is more commonly decreased in density, with a characteristic absence of trabeculae in a large portion of the bone. The bone looks as if one had made a sketch of the trabeculae with a pencil and had then rubbed out the trabeculae with the finger, leaving the smudge. The description of the lesion is more difficult than the actual appearance warrants. Once seen, they are fairly easily recognized. There is no generalized decalcification, and the uninvolved bone appears normal, in contradistinction to the lesions of hyperparathyroidism. For this

reason the bone lesions are said to be disseminated, not generalized.

Blood chemical studies show the serum calcium and phosphorus to be within normal limits. Urine calcium is not elevated, as in hyperparathyroidism. Cases with very advanced bone changes may have an elevated serum-phosphatase level.

Anatomically there are no fluid-filled cysts, but a tough fibrous tissue is found. An excellent colored picture of a skull lesion, exposed during operation, has been recently published.³¹ Histologically, osteitis fibrosa is present. Osteoclasts, however, are infrequent in comparison to the findings in hyperparathyroidism.

The etiology of the syndrome is unknown, and this fact has caused Albright and his associates to refrain from naming the disease; others have recently called it "polyostotic fibrous dysplasia."³² It does not appear to be a primary endocrinopathy. Albright has suggested the presence of an early, possibly a congenital, neurologic anomaly.

The roentgenologist plays an important role in the recognition of these cases, inasmuch as the majority of them are first seen by him, following a pathologic fracture of one of the involved bones. Unless he is acquainted with the syndrome, a series of unnecessary and dangerous procedures may follow. The lesions may be treated as bone tumors, and mutilating operations have been performed. The similarity of some of the described areas to those of hyperparathyroidism has occasioned exploration of the parathyroid glands, obviously with a negative result.

The classification of fibrocystic disease in bones has been greatly clarified by the recognition of two distinct groups: osteitis fibrosa cystica generalisata, due to hyperparathyroidism, and osteitis fibrosa cystica disseminata, as part of Albright's syndrome.

Although the etiology of the latter condition is not known, its general characteristics put it in a group similar to neurofibromatosis. There still remain single bone cysts and giant-cell tumors, the etiology and even the classification of which have not been settled, in spite of many explanatory theories.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

CASE 27261

PRESENTATION OF CASE

A thirty-seven-year-old Italian barber was admitted to the hospital complaining of weakness, fever and shortness of breath of three months' duration. Seventeen years before, at the age of twenty, the patient had a penile sore and was given a single intravenous injection. He had no further symptoms until five years before admission, when shooting pains developed in his legs. Diagnoses of neurosyphilis, syphilitic aortitis and aortic regurgitation were made, and treatment consisting of intramuscular bismuth, mercury and iodides was instituted. Spinal-fluid Wassermann and blood Hinton reactions were said to have been positive at this time. The patient continued to have occasional lightning and girdle pains, and these recurred with more severity in the three months prior to admission. At this time he developed "flu," with a nonproductive cough and loss in weight, appetite and strength. For six weeks he had noticed showers of painless red spots over his lower extremities, all of which had disappeared at the time of admission. Bouts of fever, spiking to 102°F., occurred in the afternoon and evening; they were accompanied by sweating, without chills. In addition he had noted increased nocturnal breathlessness, amounting to orthopnea, and, for two weeks, swelling of his ankles and fleeting joint pains in his knees, ankles and elbows.

The family history was negative. The patient had had scarlet fever and perhaps measles in childhood, and at the age of fifteen was told by his physician to stay in bed for six months. The patient's wife and nine-year-old child were well and gave no serologic evidence of syphilis.

Examination showed a thin, poorly nourished, pale, acutely ill man with no petechiae or clubbing of the fingers. The right pupil was large and fixed, and the left miotic and fixed to light but not to accommodation. The fundi were not remarkable. There was no venous distention, but the arterial pulsations were forceful. The apex impulse was maximal in the sixth left interspace just beyond the anterior axillary line, 11.5 cm. to the left of the midline and 3.5 cm. to the left of the midclavicular line. In the third interspace dullness extended 7 cm. to the left of the midline.

The right border of dullness was 4 cm. from the midline. Rhythm was regular at a rate of 90 to 110. The first sound was replaced by a harsh systolic murmur heard all over the precordium but maximal in the second and third left interspaces, where a faint, short, early diastolic blow was also audible. A systolic thrill was palpable in the third and fourth left interspaces, and faintly over the supraclavicular vessels. A "pistol-shot" was heard over the brachial artery. One observer heard no second heart sound, but another recorded the aortic second sound as present and equal to the pulmonic. The blood pressure in the right arm was 150 systolic, 50 diastolic, and in the left, 125 systolic, 60 diastolic. The liver and spleen were enlarged to percussion but not palpable (the patient would not co-operate on abdominal examination). Rectal examination was negative. The deep reflexes were equal and active, and the vibration and position senses were intact. In the Out Patient Department three weeks before admission, purpuric spots had been noticed over the patient's legs.

The temperature was 100°F., the pulse 90, and the respirations 22.

The urine was acid, with the specific gravity ranging from 1.004 to 1.015; there was a ++ test for albumin, and the sediment contained two or three red blood cells, five or six white blood cells and occasional granular casts per high-power field. The stools were normal. The blood showed a red-cell count of 4,000,000 with a hemoglobin of 8 gm. (photoelectric-cell technic), and a white-cell count of 7000 to 12,000; a smear showed microcytosis, anisocytosis, poikilocytosis and hypochromia. The corrected sedimentation rate was 1.1 mm. per minute. Two blood cultures showed no growth. The van den Bergh was normal, the nonprotein nitrogen 56 mg., the serum protein 6.9 gm. per 100 cc., and the carbon dioxide combining power 18.4 milliequiv. per liter. The blood Hinton and Wassermann reactions were positive, as was the spinal-fluid Wassermann reaction. The spinal-fluid protein was 26 mg. per 100 cc.; there were two lymphocytes per cubic millimeter, and the gold-sol curve was 5555331100.

An x-ray film of the chest showed marked enlargement of the left ventricle; the lung fields were clear. On fluoroscopy, the aorta showed water-hammer pulsations.

An electrocardiogram in the Out Patient Department showed no abnormal axis deviation or rhythm but a prominent S₁. A second tracing suggested digitalis effect, with a bizarre QRS₄.

The patient was very sick, ran an irregular temperature from 100 to 103°F. and was troubled

by severe epistaxes and recurrent hiccoughs. Small amounts of sulfathiazole were given, and the blood level reached 2 to 4 mg. per 100 cc. The bladder became enormously distended; foot and ankle edema persisted, and he was given digitalis and sodium citrate, the latter to correct the mild acidosis. Blood chemical studies showed continuing acidosis, with a calcium of 7.6 mg., a phosphorus of 1.9 mg. and a phosphatase of 2.2 Bodansky units per 100 cc. The plasma vitamin C was 1.1 mg. per 100 cc. A protein fractionation showed 1.7 gm. of albumin and 6.0 gm. of globulin per 100 cc.

While on sulfathiazole the patient's temperature fell to normal and remained so for three days after the omission of the drug. Nevertheless he steadily failed and died suddenly on the nineteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HOWARD B. SPRAGUE: In this case it seems as if we should have to start out with a diagnosis at the beginning and try to defend it. I think the story of the immediate illness is quite characteristic of subacute bacterial endocarditis, with what was called "flu," cough, loss of strength, showers of "red spots," fever, chills, sweating, beginning congestive failure, joint pains, two or three red cells in the urinary sediment, anemia and increased sedimentation rate; but we have not the confirmatory evidence of a positive blood culture. It does not seem as if this were the major cause of the cardiac findings. In other words this did not start *de novo* and cause the various murmurs in the heart. There was some other underlying cardiac lesion.

Of course it would be easy to take the diagnoses that had been made a year before, when he came in and was treated for syphilis. Aortic regurgitation was found at that time, and the diagnosis of syphilitic aortitis was made. The combination of syphilitic aortitis and aortic regurgitation complicated by bacterial endocarditis is very rare, although it does occur. On looking through the literature I found there had been only 5 cases reported up to 1938; 5 more were reported that year. I was rather struck with the fact that, at least in these cases, the picture was one of a free aortic regurgitation or else there was no aortic regurgitation but a bacterial invasion of the aorta above the aortic valve, sometimes with perforation. I do not know what the figures show in this hospital, but I can recall very few cases that I have seen personally in which syphilis was the underlying lesion for a *Streptococcus viridans* infection. That in itself perhaps draws me somewhat

away from a diagnosis of a syphilitic lesion of the aortic valve.

By far the commonest lesion is rheumatic, and one can distort the evidence to his own purposes in building up the diagnosis of a rheumatic lesion of the aortic valve. The patient had scarlet fever in childhood, and this must be considered as evidence of some sort of streptococcal infection. We believe nowadays that, if a person has rheumatic heart disease following scarlet fever, he had rheumatic fever at the time he had the scarlet fever. This patient was told to go to bed for six months when he was fifteen years old. I do not know just why a doctor might tell a fifteen-year-old boy to go to bed for six months, but I should think it might have been the finding of something wrong with his heart. There is the suggestion that he had rheumatic infection.

On physical examination he had a harsh systolic murmur replacing the first sound, maximal in the second and third spaces, but they noted only a faint diastolic blowing murmur. Although I get the impression that this man had rather marked arterial pulsations, the description of the cardiac findings is not that of the characteristic loud to-and-fro aortic regurgitation of syphilis. There was a systolic thrill felt in the third and fourth interspaces and in the supraclavicular vessels. That is, of course, suggestive evidence of some degree of obstruction of the aortic valve. It could be due either to a chronic rheumatic involvement with some interadherence of the cusps or to complicating bacterial vegetations. We can use the description of the aortic second sound here any way we want to. For my "rheumatic" purposes it was absent.

The laboratory studies, particularly the x-ray films and electrocardiogram, showed a big left ventricle; nothing is said about the auricles, which I presume were not demonstrably enlarged. The lung fields were clear, and there were said to be water-hammer pulsations in the aorta. The electrocardiogram makes me suspicious of a pure aortic lesion. There was a normal electrical axis. Again I am not sure, and I commend it to our staff perhaps to look up, whether or not we have had any cases of free aortic regurgitation due to syphilis in which we did not have evidence of left-axis deviation by electrocardiogram, unless it was complicated by something else. If one is supporting a rheumatic story, one would suggest that there also was a mitral lesion to give a compensating right-ventricular effect on the electrocardiogram. Another thing that is somewhat against this being a primary syphilitic process is that the diagnosis was made five years before

entry, and he proceeded to live along about as usual, I should say, until he acquired some sort of infection. He did not go rapidly downhill the way so many patients with syphilitic aortitis do when the aortic valve and the regions of the coronary ostia are involved, and he lived longer than the average patient with syphilitic aortitis after the diagnosis of the valve lesion.

I suppose I should wonder whether he had a congenital heart. The likely types would be interventricular septal defect or patent ductus arteriosus. A patent ductus arteriosus might cause some of the peripheral signs of aortic regurgitation, but an interventricular septal defect would not, nor is the description of the murmurs at all suggestive of patent ductus arteriosus. I think I have to make a diagnosis of an underlying rheumatic heart, with aortic regurgitation and some degree of stenosis. Whether the stenotic element was of a rheumatic nature or due to bacterial vegetations, I do not know. I am also going to guess that Dr. Mallory found some involvement of the mitral valve, with mitral regurgitation, and that there was a superimposed subacute bacterial endocarditis, at least on the aortic valve.

I am left with the question what to say about syphilis in this case. It appears that the patient had syphilis, including infection of the central nervous system, but I can only guess that, on the law of probability, there were syphilitic lesions in the aorta; so I might as well put it in for good measure. He died suddenly with a combination of congestive failure and some other factor that might have been embolic. There is nothing on which I can make a diagnosis of the terminal event.

Parenthetically, I should like to make one short note about "water-hammer pulsations." In deference to the members of the X-ray Department, whom I respect very much, the term "water hammer" refers to something you can palpate, not something you can see. Corrigan, when he described water-hammer pulse, was familiar with a scientific instrument called the water hammer. When I ask physicians what this is, they usually say it is the noise in steam-radiator pipes, or has something to do with a hydraulic ram. In reality, a water hammer is an instrument that has been used by teachers of physics for many years, to illustrate the falling of liquids in a vacuum. The water rises and falls in a mass and gives a sensation of shock to the palpating hand and an audible blow as it strikes the bottom of the tube.

DR. JAMES R. LINGLEY: The films showed

marked enlargement of the heart, as described, the enlargement being almost entirely left ventricular. In this oblique view one sees no auricular enlargement. The aorta is certainly not dilated. In fact, it appears to be rather small. The lungs are clear. There is no evidence of coarctation. I think the x-ray appearance bears out Dr. Sprague's diagnosis of an aortic-valve lesion, more likely rheumatic than syphilitic. It would certainly be unusual to have a small aorta in syphilitic aortitis.

DR. PAUL D. WHITE: Have you any comment to make about the blood-pressure difference in the arms?

DR. SPRAGUE: I thought that was more than we ordinarily see, but I cannot find enough in the aorta by x-ray or physical examination to explain it.

DR. WYMAN RICHARDSON: There was a great deal of disagreement about this case. Dr. Dieuaide and Dr. Bland are here, and they can express their opinions later. We all agreed that he had bacterial endocarditis. I thought the patient had rheumatic heart disease by somewhat the same, but not so good, reasoning as that of Dr. Sprague. Several things interested us. One was the manner of death; another was the urinary situation. The patient appeared to be uremic, and whether that was due to stasis or to nephritis associated with bacterial endocarditis I was not sure. The anemia was unusual and looked more like hereditary Mediterranean anemia than that due to an infection. I hesitated to speak of that because so many other things were running through this case. The albumin-globulin ratio was rather curious and caused a good deal of comment, but we still did not, I think, lay a great deal of stress on it. It suggests the possibility of liver disease.

DR. FRANCIS R. DIEUAIDE: I should like to differ mildly with a portion of Dr. Sprague's analysis, in that I think this thing he calls a rarity, that is, bacterial endocarditis in association with syphilitic disease of the aorta, depends entirely on how much we see of the latter disease. There were three series of cases reported last year,¹⁻³ and I know from my own experience that one sees much more of it in localities where there is a good deal more syphilis than there is here. I should not like to call the combination rare. Secondly, one has to be careful about putting too much weight on the x-ray appearance of the aorta, because we have had the experience of finding even aneurysms of the first portion of the aorta when the rest of the aorta is not involved. It is no great rarity for *syphilitic aortitis to be very patchy, and sometimes the ring of the aorta is extensively de-*

stroyed without spread of the involvement upward. So although I agree in general with Dr. Sprague's reasoning about the case, I think the argument for syphilitic aortitis with involvement of the valve ring is a fairly good one. Also I do not believe that the course of syphilitic aortitis even with involvement of the ring or valve to the point that the peripheral signs of regurgitation occur, is necessarily so short. In the past we have not seen these patients very often until they had symptoms of failure. Now in the large clinics for the treatment of syphilis, where patients are brought in willy nilly because of positive serologic tests, frequently with no symptoms whatever, we are seeing more patients in whom the early diagnosis of regurgitation can be made. I agree that the course is very short, once important signs of cardiac insufficiency appear, but I think we know very little about the preceding course, which probably runs for a fairly long period of time in a great many cases.

DR EDWARD F. BLAND: There is not much to say except there was one physical sign that disturbed us a good deal: the thrill was much more impressive than one might suspect from reading the description here. It was well marked and clearly localized in the third and fourth left interspaces near the sternum and could not be felt at the base of the heart. The vibrations over the vessels at the base of the neck were hardly more than one might expect with this degree of widening of the pulse pressure. At first glance several of us considered very seriously the possibility of some congenital lesion but hesitated to bring it into this already complicated picture. Dr. Reno Porter, when he saw the patient in the Out Patient Department prior to admission to the ward, first suggested an interventricular septal defect complicating an extensive involvement of the aortic valve. We considered the further possibility of a complicating patency of the ductus arteriosus, but absence of a prominence of the pulmonary cone, among other findings, forced us to discard this diagnosis. We continued to watch for pulmonary infarcts as supporting evidence of either a patent interventricular septum or ductus, but none were recognized. At the end I think the weight of opinion was that this was predominantly an obstructive lesion at the aortic valve, probably rheumatic in origin, with superimposed bacterial endocarditis.

DR EARLE M. CHAPMAN: Why could it not have been pulmonary stenosis rather than aortic?

DR BLAND: There was nothing clearly to suggest it,—no evidence of right-axis deviation in the electrocardiogram and no cyanosis,—and all

the peripheral signs pointed to deformity of the aortic valve.

CLINICAL DIAGNOSES

Central nervous system syphilis
Aortic regurgitation, ? type
Subacute bacterial endocarditis
Nephritis, ? type
Syphilis of liver?

DR SPRAGUE'S DIAGNOSES

Rheumatic heart disease, with aortic regurgitation and stenosis (and probably mitral regurgitation).
Subacute bacterial endocarditis
Syphilitic aortitis

ANATOMICAL DIAGNOSES

Congenital heart disease: interventricular septal defect, ? bicuspid aortic valve.
Probable rheumatic heart disease, with aortic stenosis
Subacute bacterial endocarditis: aortic valve and septal defect
Syphilitic aortitis
Septic infarction of the lungs
Chronic passive congestion
Tabes dorsalis

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: There was an obvious bacterial endocarditis, but the real question, of course, concerns the substratum on which it had developed. The aorta showed patchy scarring, which was grossly and microscopically quite characteristic of syphilis. It stopped abruptly, however, several millimeters above the commissures and coronary ostia. The aortic cusps instead of being separated were fused with dense fibrous tissue. At one commissure this fusion was so complete as to be suggestive of a congenital bicuspid valve. The other commissure looked more like an old rheumatic lesion, and was so diagnosed despite the fact that the mitral valve was negative. Overlying the chronic changes were fresh vegetations characteristic of bacterial endocarditis. When the heart was first examined we were surprised by the fact that the right ventricle was very much hypertrophied, proportionately quite as much or more than the left, a finding that accounts, of course, for the lack of axis deviation. Not until the valve leaflets were reflected did we discover a small interventricular septal defect, with bacterial vegetations clustered about the mouth in each ventricle. We did find two small septic infarcts in the lungs but no major pulmonary embolus. This patient unquestionably had syphilis of the

mia, leukocytosis and lowered serum protein. Furthermore, pancreatic cysts occur more frequently in women than in men, and the maximum incidence is between twenty and forty years of age. I shall refrain from speculating on the particular type of pancreatic cyst this one is—whether a cystic adenoma, a hemangioma or a simple retention cyst—and limit myself to the statement that the surgeon found a large pancreatic cyst filled with blood.

DR. GRANTLEY W. TAYLOR: Dr. Rogers has said that a pancreatic cyst traditionally presents between the colon and stomach. Quite obviously this stomach is pushed down, and the cyst is above the stomach. I think that pancreatic cysts very frequently occupy the position that this one does and that they do not usually or commonly present below.

DR. ROGERS: Whipple* states that, although some go down into the pelvis and some present above the stomach, the majority are between the stomach and colon. He had 133 cases, in which more than half the cysts were exactly in the midline, with about 40 per cent slightly to the left and only 10 per cent slightly to the right; they occurred at varying levels, but almost all were in the upper abdomen.

DR. JOHN D. STEWART: I should like to ask Dr. Rogers if he has any difficulty explaining the fever and leukocytosis on the basis of the diagnosis he has made.

DR. ROGERS: Those are the only things that stick in my throat, and I am assuming that the presence of the hemorrhage is responsible for them. Of course you cannot tell without any past history whether the patient might not have had some other coexisting condition that would account for anemia, leukocytosis and, possibly, fever. She was in the last day of her menstrual period, of course, but I am hoping that sudden severe hemorrhage into the cyst would account for all the blood findings.

DR. TRACY B. MALLORY: Acute external hemorrhage severe enough to produce a red-cell count of 2,500,000 will account for a considerable leukocytosis.

DR. STEWART: And give a temperature of 102° F.?

DR. MALLORY: If it were external it would not elevate the temperature.

Another point, the hemoglobin of 80 per cent

is manifestly impossible, but it must have been relatively high in comparison to the red-cell count, a finding that suggests a very acute hemorrhage.

DR. EDWIN L. CANTLON: This patient came into the Emergency Ward at night, and although we did not think of the myriad of things Dr. Rogers has mentioned, we came to the same conclusion that he did and operated on her a couple of hours after admission. We found exactly what Dr. Rogers has described—a large cyst of the pancreas, which was presenting through the gastrohepatic ligament. The thing that was a bit hard to explain was the fact that the peritoneal cavity was full of fresh blood, a condition that we did not suspect from clinical examination. The blood was coming out of the foramen of Winslow, and a finger introduced into the foramen very quickly confirmed the impression that the mass was in the pancreas. By separating the gastrohepatic ligament it was easily removed. The bleeding points in the pancreas were readily stopped with atraumatic sutures.

CLINICAL DIAGNOSIS

Hemorrhage into cyst of pancreas.

DR. ROGERS'S DIAGNOSIS

Hemorrhagic cyst of pancreas.

ANATOMICAL DIAGNOSIS

Papillary adenocystoma of the pancreas, with hemorrhage.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The cyst that Dr. Cantlon resected was lined with epithelium and showed numerous papillary processes, being essentially similar to the cyst in the case that was presented about a month ago. It did not appear to be very rapidly growing, but experience leads one to believe that epithelial cysts containing many papillary processes, whatever their origin, are potentially malignant. I am not willing to give an unqualifiedly good prognosis for this patient. The cyst was markedly distended with fairly fresh blood clot.

DR. ROGERS: Do you think the cyst had been there for a long time, undiscovered?

DR. MALLORY: I should certainly think it must have been present for months at least. Probably it was fairly small until it was distended by the hemorrhage.

A STATE HOSPITAL FOR THE CARE OF PSYCHOTIC CHILDREN

THE desirability of establishing a hospital for the care of mentally ill children has long been in the minds of many physicians in Massachusetts. At present, there is no such provision. Not many children, to be sure, break down mentally compared with the vast number of adults who apply yearly for care. In 1939, for example, only one hundred children under fifteen years of age were admitted to state hospitals for mental diseases in Massachusetts. About ten of them had epilepsy and were adequately cared for at the Monson State Hospital. The ninety had to find whatever accommodations they could in the other state institutions.

These one hundred children, however, do not

belong in buildings designed and serviced for adults. They should be cared for in separate buildings, or at least in isolated wards, with special nurses and psychiatrists, who are interested particularly in the behavior disorders of childhood. This has long been recognized by other states such as New York, where three hospitals have special provisions for juveniles. An even better example is the endowed Bradley Home at East Providence, Rhode Island, a pioneer hospital for children's behavior disorders, where a great deal of valuable work has been done in the last few years to elucidate some of the problems connected with the psychotic child. A similar institution was established some years ago in Philadelphia, particularly dealing with those children showing behavior disorders after encephalitis lethargica.

A movement for a special hospital in Massachusetts is backed by the Massachusetts Department of Mental Health and also by the Massachusetts Society for Mental Hygiene. In the publication of the latter organization for January, 1941, facts will be found summarizing the situation. The Department of Mental Health has for many years requested funds to establish a children's unit on the grounds of the Metropolitan State Hospital at Waltham. The legislature of Massachusetts has never acted favorably on this suggestion, but it is hoped that when the facts and the opinions are clearly presented and better known, this important matter will not long be delayed.

THE MICROFILM SERVICE OF THE ARMY MEDICAL LIBRARY

THE Army Medical Library, in Washington, has recently inaugurated Microfilm Service for the benefit of physicians throughout the country, a microfilm being a strip of 35 mm motion picture film with images of printed pages photographed on it in sequence. By this method, any article in any one of the 4034 current medical periodicals taken by the library can be obtained in microfilm copies at a very reasonable price. The charge is 30

cents for each complete article not exceeding thirty pages in length, and 10 cents for each succeeding ten pages or fraction thereof. Thus, an article can be obtained quickly for reading on a microfilm projector. This is particularly valuable for articles appearing in obscure and rare journals. Many of the small medical libraries do not take more than 200 or 300 current periodicals. The large libraries, such as the Boston Medical Library, take 800 or 900, but even this is small when compared with those taken at the Army Medical Library. The films may be projected and read with a small hand projector; however, in most libraries, large machines are available, which throw the pages on a screen two or three feet in size.

How does one find out about an article that is not likely to come to one's attention? To supplement the microfilm service, the Army Medical Library has added another of great importance to the medical profession. A weekly bulletin, *Current List of Medical Literature*, is published. Divided into large subjects, the literature of the week, as received in the Army Medical Library, is listed by the titles of articles occurring in medical periodicals. Thus, by watching one of the forty-four general classifications, a physician interested in keeping current with a special subject can quickly pick up references to that topic in any published periodical received by the library. The lists cover practically all the printed medical matter in the world. In many cases, of course, the periodical may be at hand in his own office or in his own medical library. In cases where this is not so, the Army Medical Library offers a solution for quickly bringing him the article in question. For the research worker, this brings medical literature to his desk almost immediately, three to six months before he could find it in an index, such as the *Quarterly Cumulative Index Medicus*.

Both these services are run by the Friends of the Army Medical Library. The library co-operated by providing the necessary space for the work, and by supplying the publications from which the

microfilm copies are made. The only cost to the user is for actual labor and material required in making and distributing the microfilm copies. For the *Current List of Medical Literature*, a charge of \$5.00 a year is made, which it is hoped will cover the cost of issuing this weekly bulletin. It should be pointed out, moreover, that occasionally, in addition to the current list of periodicals, a list of books received in a period of a month or six weeks at the Army Medical Library is also given to subscribers without additional charge.

Thus the Army Medical Library, the largest and most efficient in the world, becomes a national medical library, serving the medical profession throughout the land. To many, such a course has long been a cherished ideal. With a new building in sight for the library and with an expanding service, the medical profession should be appreciative of the fact that the Army Medical Library is alive to the present needs of the profession.

MEDICAL EPONYM

HUNTERIAN CHANCRE

On page 218 of the volume, *A Treatise on the Venereal Disease* (London, 1786) by John Hunter (1728-1793), the following description appears:

This, like most other inflammations which terminate in ulcers, begins first with an itching in the part; if it is the glans that is inflamed, generally a small pimple appears full of matter, without much hardness, or seeming inflammation, and with very little tumefaction, the glans not being so readily tumefied from inflammation as many parts are, especially the prepuce; nor are the chancres attended with so much pain or inconvenience, as those on the prepuce; but if upon the fraenum, and more especially the prepuce, an inflammation more considerable than the former soon follows. . . . The itching is gradually changed to pain; the surface of the prepuce is in some cases excoriated, and afterwards ulcerates; in others a small pimple, or abscess, appears as on the glans, which forms an ulcer. A thickening of the part comes on, which at first, and while of the true venereal kind, is very circumscribed, not diffusing itself gradually and imperceptibly into the surrounding parts, but terminating rather abruptly. Its base is hard, and the edges a little prominent. When it begins on the fraenum, or near it, that part is very commonly wholly destroyed, or a hole is often ulcerated through it.

TOXIC SEPARATION OF THE
PLACENTA, WITH DEATH

A thirty-five year-old para IV, when about thirty-seven weeks pregnant, was sent into the hospital because of a large trace of albumin in the urine and a blood pressure of 170 systolic. She remained there two days and was sent home apparently improved. She was not seen again until three weeks later, when she came into the hospital in active labor; there was profuse vaginal hemorrhage, and the patient was unable to see.

There was no history of scarlet fever. The three previous pregnancies were not described in the record; all three children were living and well. The prenatal care had been inadequate.

Physical examination at the time of the second admission was essentially negative. The heart was not enlarged, there were no murmurs. The pelvic measurements were normal. Although the blood pressure was not recorded, it was probably high, since the urine showed a large trace of albumin. The uterus was enlarged to the size of a full term pregnancy, the patient was in labor. No fetal heart could be heard. Vaginal examination showed the cervix to be dilated to admit four fingers, no placenta was felt, and the patient was bleeding profusely. A diagnosis of separation of the placenta at term was made. Dilatation of the cervix was completed under ether anesthesia and a version was accomplished. The placenta came away with the stillborn baby. The uterus was packed with gauze, and intravenous glucose was given. The patient was sent for transfusion but died before it could be started.

Comment. This is a typical case of toxic separation of the placenta. This patient should never have been discharged from the hospital after only two days of treatment. It is possible that, had she been examined at the time of the first admission, the cervix might have been found to be favorable for elective induction by rupture of the membranes. If this had been possible, the subsequent fatal result probably would not have developed. If the patient had been treated more conservatively at the time of the second admission,—that is, by rup-

turing the membranes, using small amounts of pituitary extract, and giving a transfusion,—it is probable that normal delivery could have been effected without the shock attendant on dilatation of the cervix and internal podalic version; with such a degree of dilatation it is unlikely that a cervical pack and Spanish windlass would have been necessary. She was a very sick patient when she arrived in the hospital, and it is only barely possible that more conservative handling would have prevented the fatality.

DEATHS

ANDREWS—HAROLD ANDREWS, M.D., of Boston, died June 9. He was in his sixty-ninth year.

Dr. Andrews received his degree from the Harvard Medical School in 1896. He was a fellow of the Massachusetts Medical Society and the American Medical Association, and was a member of the New England Obstetrical and Gynecological Society and the American College of Surgeons.

NORTON—GEORGE P. NORTON, M.D., of Fitchburg, died June 12. He was in his sixty-eighth year.

Dr. Norton received his degree from the Bellevue Hospital Medical College in 1895 and was on the staff of the Hurlburt Hospital, Fitchburg, for twenty-nine years. A former city physician and district medical examiner, he was, at the time of his death, chief medical examiner for the draft board under the Selective Service Act.

He was a member of the Massachusetts Medical Society, having been a president of the Worcester North District Medical Society, and was a member of the American Medical Association.

His widow, two sons, a daughter and a grandchild survive him.

CORRESPONDENCE

ILLUMINATION AND EYE HEALTH

To the Editor. For more than a quarter of a century our laboratory has been engaged in research aimed to provide a scientific foundation for the utilization of light and lighting as essential partners of vision and as controllable aids to seeing. With adequate facilities and without restrictions in scientific endeavor, characteristic of the research laboratories of the General Electric Company, the personnel devoted to this work has created a formidable structure, properly termed the "science of seeing." This term is used in order to distinguish it from the narrower science of physiologic optics which the more extended science includes. These researches have been conducted over a broad front and have contributed much toward easier seeing through a better understanding of the efficacy of light and lighting and other aids to seeing which influence the efficiency, comfort and welfare of human beings.

In the March 13 issue of the *New England Journal of Medicine*, Dr. David G. Coggin, not without dogmatism, naïveté and some sarcasm, apparently attempts to discredit the entire scientific structure which the researches of our laboratory have built. The absence of scientific spirit and method in his critique is further emphasized by implications that our motives are questionable. It should be obvious to those acquainted with the variety and number of researches in seeing prosecuted in our

*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section.

laboratory that our work cannot be adequately discussed in a four-page paper such as that of Dr. Cogan. Neither can it be adequately discussed if the critic is inadequately familiar with it.

Statistics pertaining to the prevalence of defective vision are appalling and they should appeal to the interest of any profession or group which is in a position to lighten the visual burdens in our modern world in which critical tasks have been greatly multiplied in number and in duration. Such statistics should be particularly appealing to ophthalmologists, but Dr. Cogan seems to be more concerned with attempting to prove that poor lighting does not harm the eyes and that better lighting than has prevailed is unnecessary. In this respect his attitude is quite opposed to that of many distinguished members of his profession. (Lancaster, W. B. Ocular symptoms of faulty illumination. *Am. J. Ophthalm.* 15: 783-788, 1932. Jackson, E. Light for ocular health and efficiency. *Am. J. Ophthalm.* 18:374, 1935.)

Ignoring the sarcasm in his statement that the public has been subjected to a "research offensive" and that we have "inundated" various journals with technical papers bringing to the attention of professions and public the results of our researches, we admit feelings of gratitude and satisfaction for having had the opportunity to work so long in a field so important in modern civilization. The opportunity is still large, and it has always been open to others.

It is difficult and perhaps impossible to prove that poor illumination, combined with prolonged and critical seeing of near-vision tasks, directly harms the eyes. Certainly such conditions could not possibly be favorable to the eyes. However, the inability to obtain direct evidence is not uncommon in many sciences which deal with the welfare of human beings, such as the science of medicine. Much evidence must be indirect, and in the case of eyes, if one fairly views all the indirect evidence, he can hardly avoid the decision to utilize every controllable aid to seeing, whether it is type-size, light, eyeglasses, lighting or vitamins, to help reduce the severity of modern seeing. If Dr. Cogan will review the literature dealing with the foregoing aids to seeing, we are sure he will find that other professions are confronted with difficulties in supplying rigid and incontestable proofs of many accepted practices and principles.

Admittedly, we obtained much encouragement in deciding many years ago to devote a substantial part of our laboratory facilities to these researches, by broadly considering the evolution of human eyes and human beings under outdoor environmental factors, such as brightness-levels, quality of daylight and character of natural lighting. Nature is an inspiring textbook in the absence of knowledge, but we have never entertained the belief that philosophy per se proves anything. Nevertheless, theories are necessary in scientific work as temporary lines of communication between the known and the unknown; and they are also of value in encouraging researchers to invade this or that unknown. Beginning with such a view, we naturally explored the realm of physiologic optics and found that light (or more properly brightness) had been seldom considered or adequately utilized as a controlled variable and that lighting was almost entirely ignored. This left gaps in that field which it was necessary to fill. We filled some of these by giving light its proper place as an aid to seeing.

One result of our researches was to reveal that the criterion of visual acuity (as measured by the usual high-contrast objects) is not all-important. The ophthalmologist uses this function effectively to determine refractive

errors, and as a consequence he naturally thinks largely in terms of threshold-size. In many tasks the criterion of visual acuity is relatively inappropriate, as, for example, in tasks involving low contrasts. Nevertheless, it is interesting to note in this connection that Dr. Cogan states that visual acuity reaches a maximum at about 10 footcandles. This is not true, even for black objects on white backgrounds, as has been known since the time of Koenig. Actually in such cases, visual acuity is still increasing after an illumination of 100 footcandles has been reached. However, here it is well to emphasize that *illumination* and *brightness* are two different factors; and if a black test-object is viewed, not on a white background which diffusely reflects 80 per cent of the incident light, but on a gray background which diffusely reflects only 8 per cent of the light, the same brightness of background produced by 100 footcandles on a white background is produced by 1000 footcandles on a dark-gray background. It should be recognized that the backgrounds against which objects are seen in innumerable situations in the work-world, in the school and in the home do not provide high contrasts. What then becomes of Dr. Cogan's standard of 10 footcandles for maximal visual acuity? Obviously it is meaningless in itself and absurd as a categorical statement.

Turning to visibility, we are concerned with one of two fundamental aspects involved in every task of critical seeing. One is the visibility of the task and the other is ease of seeing or performing the task. In 1928, we completed an extensive research which established the relations among the four fundamental factors of the visual threshold—size, contrast, brightness and time. The Luckiesh-Moss Visibility Meter has been built upon an adequate foundation of knowledge of these relations. The time factor may be introduced if one desires. The relations of these fundamental factors are involved in the unit and scales of visibility which we have created. By means of this device we can measure visibility in terms of a scale of size or in terms of a scale of contrast. It does not matter particularly what scale or unit is used so long as the user understands the scale he is using, although some scales are simpler than others. The important matter is to be able to measure visibility in understandable terms. That we can do. In a world dependent overwhelmingly on visibility of objects there has been no practical means of measuring visibility. Obviously it is impractical to dissect a visual object or visual task into its component parts. Any contribution of this sort is entitled to encouraging consideration and constructive criticism. Already this device has been welcomed with enthusiasm in a variety of researches and practices beyond the important realms of the science and practice of lighting.

The Luckiesh-Moss Visibility Meter does not determine the footcandles "necessary" for any visual task as Dr. Cogan has stated. It merely determines the visibility of an object or task under any seeing conditions in terms of a meaningful unit and scale of visibility. Also the visibility of an object or task can be determined in terms of the visibility of a specific task, such as reading under specified conditions. By this means it is possible to make a difficult task of seeing of the same visibility as an easier task of seeing by taking advantage of any controllable aid to seeing, such as light and lighting. All tasks which are visible are not equally visible. However, it is possible to make many of them equally visible. Anyone is at liberty to determine his own "standard" of visibility, and by means of this visibility meter, to explore the realm of suprathreshold visibility, the important

world of everyday seeing which is completely ignored in considerations confined to thresholds

Dr Cogan devotes one paragraph to the extensive and important realm of psychophysiologic effects of seeing which our researches specifically invaded to supply a foundation of knowledge for ease of seeing. These researches invaded not only an unknown realm but one which had been almost completely ignored. The observed physiologic effects of seeing when correlated into a structure, form a highly integrated one. Of great practical importance is the fact that these researches have led to the development of certain criteria of ease of seeing which have been sorely needed. One in particular is the rate of involuntary blinking. We have used this criterion in more than a score of major researches not only in the realm of light and lighting but in other realms, such as typography and ocular refraction. The result is we now have a criterion of ease of seeing which is not only sensitive throughout a variety of applications, but which has meaning. In a few references which Dr Cogan mentions in opposition, he does not discuss the criteria used, which obviously are all important in interpreting results.

We have discussed a few aspects of Dr Cogan's article for the purpose of calling the reader's attention to the extensive structure which is described as the science of seeing and, particularly, to its complexity and to its contributions in various phases of civilized activities involving visibility and ease of seeing. This structure cannot be properly appraised by ignoring the data and criteria involved. Toward the end of Dr Cogan's discussion he reveals an inadequacy of concept in the statement, 'There is no valid reason for believing that man cannot judge the amount of illumination that gives him easy and comfortable seeing.' Such a possibility is just as far beyond the ability of a human being in respect to light and lighting as it is beyond his ability to specify, by means of his unaided senses, optimum conditions pertaining to such factors as diet, hygiene and eyeglasses. We do not believe that Dr Cogan would admit that one could or should choose his own eyeglasses solely on the basis of introspection by the patient. Almost all progress in science is due to devices which have aided human senses, and practically all progress has been achieved since man learned not to rely solely on his senses. Furthermore, much of the great mass of scientific knowledge available today has come from the realm of the unobvious which simply means that vast realm beyond the reach of our unaided senses.

MATTHEW LUCKIESH
FRANK K. MOSS

Lighting Research Laboratory
General Electric Company
Nela Park, Cleveland

The above letter was submitted to Dr Cogan and the following reply was received:

To the Editor: The article referred to in the foregoing letter was one of the 'Medical Progress' series presenting an annotated analysis of the literature pertaining to illumination and eye health. It was specifically pointed out that there was little foundation for the widespread belief that damage to the eyes comes from low illumination, and since this misconception and much of the present campaign for more and more light is based on the researches of Luckiesh and Moss, their work was critically examined. The characterization of their work as a 'research offensive,' to which they now take exception, was not mine but was quoted from one of their own texts.

Statistics pertaining to the prevalence of defective vi-

sion are, as noted in the foregoing letter, appalling, but it is not apparent that this has anything to do with illumination. None of the usual lists of defective vision include, so far as I am aware, anything about faulty illumination as a cause. Since the authors now admit in this letter—and to my knowledge it is the first time they have done so in print—that it is impossible to prove that poor illumination harms the eyes, the authors should cease threatening the public with permanent injury, 'tragic toll' and deeply hidden penalties, which they have previously claimed come from inadequate illumination.

Their objection to the stated amounts of illumination necessary for maximum visual acuity and so forth are not issues with the reviewer but with the investigators cited in the article and it seems only scientifically appropriate that these investigators merit some recognition in the all inclusive 'science of seeing.'

I do not believe that the letter by Luckiesh and Moss should go without answer for while the subject may not seem of great importance to the reader, it is, in view of the medical implications with which it has been enshrouded, of sufficient concern to be taken seriously. It is especially desirable that the real issues be kept as free as possible of unnecessary verbalism and that adequate counsel in matters pertaining to medicine be made available to the public.

DAVID G. COGAN, M.D.

Howe Laboratory of Ophthalmology
243 Charles Street
Boston

NOTICES

ANNOUNCEMENT

DR ALLEN G. RICE announces the removal of his office on July 1 from 33 School Street, Springfield, to 146 Chestnut Street, Springfield.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS, UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Haverhill	July 2	William T. Green
Gardner	July 8	Mark H. Rogers
Brockton	July 10	George W. Van Gorder
Northampton	July 15	Garry deN. Hough, Jr.

Fall River	July 28	Eugene A. McCarthy
Hyannis	July 29	Paul L. Norton

EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

Examinations for appointment as assistant surgeon (lieutenant junior grade), United States Navy Medical Corps, will be held at all the large naval hospitals and the Naval Medical Center, Washington D. C., on August 11 to 15 inclusive, October 6 to 9, inclusive, and January 5 to 9, 1942, inclusive.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment and graduates of Class A medical schools who have completed at least one year of in-

SUBJECT INDEX

A

- ABDOMINAL surgery [Allen] *159
 ABSCESS, multiple, of liver [Faxon & others] 611-cr
 ACETONE in urine, simple micromethod for detection of [Brem] *462
 ADENOCARCINOMA, primary, Fallopian tube [Gregg & others] 427-cr
 primary, of jejunum [Hunt & Kaneb] *353
 of transverse colon [Daland & others] 384-cr
 ADENOCYSTOMA, papillary, of the pancreas [Young & others] 988-cr
 ADENOMA of pancreatic islet cells [Harwood & others] 659-cr
 testicular of ovary [Fremont-Smith & others] 694-cr
 ADRENAL cortex in health and disease [Aub] *857
 AID for physicians' children in England. 345-misc
 ALCOHOL, sale of, in Massachusetts 777-c
 ALCOHOLIC cirrhosis of liver [Urmy & others] 333-cr
 ALCOHOLISM, problem of 869-c
 some contemporary opinions [Moore] *848
